Extreme care must be taken when using stainless steels in the 98 to 100% concentration range at high temperatures as velocity conditions, reductions in acid concentration, or changes in oxidant levels may initiate high corrosion rates. For contrast, compare the higher corrosion rates generated in flowing 98.7% H_2SO_4 at 100 °C (212 °F) shown in Table 2 (Ref 25) with the data for generally static conditions in Table 1. In the oleum range, stainless steels with higher chromium and low-to-nil molybdenum are free from concerns about minor acid concentration variations, and corrosion resistance is extended well in excess of 100 °C (212 °F).

Anodic protection is a practical method of extending the useful temperature and concentration range for stainless steels in H_2SO_4 . Nearly all new acid coolers are built with anodic protection. With anodic protection, a stainless steel component (anode) is held in the passive condition by an impressed current from a cathode. Fortunately, H_2SO_4 is a good conductor of electricity and therefore has good throwing power. Complex shell sides of stainless steel shell and tube coolers handling concentrated H_2SO_4 can be easily protected using alloy C-276 cathodes that extend the full length of the tube bundle. In these units, the tubes joints are welded, not rolled, so that anodic current can protect the tube to tubesheet crevice. Piping is more difficult to protect because the current must be thrown a greater distance from the cathodes,

Table 1 Corrosion rates of various metals in 99% H_2SO_4 at 100–120 °C (212–250 °F)

which are typically located every 4.5 to 6 m (15 to 20 ft). Stainless steel may be protected in 93% H_2SO_4 up to 60 to 70 °C (140 to 158 °F) and in 98 to 99% H_2SO_4 up to 120 °C (248 °F). Corrosion rates can be reduced to 0.01 to 0.1 mm/yr (0.4 to 4 mils/yr).

Silicon Stainless Steels. Austenitic stainless steels containing 5 to 6% Si have been developed for concentrated H_2SO_4 service. Cast and wrought versions are available. The cast version, UNS J93900, has a typical composition of Fe-5Si-21Cr-16Ni-0.02C (Ref 26). The wrought version of this alloy UNS S30601 has a typical composition of Fe-5.3Si-18Cr-18Ni-0.02C. The wrought alloy has shown useful corrosion resistance in 93% H_2SO_4 up to 70 °C (158 °F) and in 99% H_2SO_4 up to 120 °C (248 °F) without anodic protection. Anodic protection extends the temperature and concentration limits. UNS S32615 and UNS S38815 are other high-silicon stainless steels reported to have resistance to hot concentrated acid. Over the last 20 years, piping, distributors, pump tanks, coolers, and absorbing towers handling hot 93 to 99% H_2SO_4 have been made from silicon stainless steels.

Corrosion protection is obtained by the formation of a tenacious silicon-rich film formed on the surface during the initial days of corrosion. The silicon-rich film is attacked by oleum and the corrosion resistance is destroyed. Severe corrosion has occurred in absorbing towers where stagnant acid touching the wall in and below the packing area was locally enriched in SO_3 , allowing oleum formation. The silicon stainless steel alloy manufacturer should be consulted for the specifics of the alloy performance.

Cast stainless steels have essentially the same corrosion resistance to H_2SO_4 as their wrought counterparts. Because the cast versions contain second-phase ferrite for castability, care must be taken that proper heat treatment is performed for maximum corrosion resistance. Preferential corrosion as the result of the duplex structure has been shown to be a problem. However, properly cast and heat treated duplex materials perform well (Ref 15).

One cast alloy that does not have a close wrought counterpart is ACI CD-4MCu (UNS J93370). Its corrosion resistance lies between alloy 20Cb-3 and type 316. Figure 7 shows the isocorrosion diagram for this cast alloy. Useful corrosion resistance, less than 0.5 mm/yr (20 mils/yr), of CD-4MCu in H_2SO_4 extends over the entire concentration range at ambient temperatures, and the alloy is used well above 100 °C (212 °F) in oleum service.

Higher Austenitic Stainless Steels

Like the austenitic stainless steels, the corrosion resistance of the higher austenitic stainless steels is also complex. However, the range of passivity and corrosion resistance is extended because of the higher alloy content. Like the stainless steels, active and active-passive electrochemical behavior are the modes of corrosion.

Resistance is achieved in the passive state. A summary that includes corrosion data is provided in Ref 15.

The 20-type alloys are usually the first considered when an H_2SO_4 environment is too corrosive for the use of steel, 300 series stainless steels, or cast iron. This group contains both wrought alloy 20Cb-3 (N08020) and cast alloy ACI CN-7M (N08007) that are roughly equivalent in resistance to H_2SO_4 . These alloys contain 20Cr-30/34Ni-2.5Mo-2.5Cu-bal Fe.

Cast ACI CN-7M. Figure 8 shows an isocorrosion diagram for cast ACI CN-7M. This alloy is generally suitable to 80 °C (175 °F) at concentrations to 50%. For higher concentrations, good corrosion resistance is expected to 65 °C (150 °F).

Wrought Alloy 20Cb-3. The wrought counterpart to cast ACI CN-7M was developed in 1947. In 1948, niobium was added to this alloy for stabilization against sensitization and intergranular attack. In 1963, the nickel content was raised to 33 to 35% in order to give greater resistance to chloride stress-corrosion cracking (SCC) and to improve resistance to boiling H_2SO_4 under heat-transfer conditions. Minor changes were subsequently made to impart greater resistance to intergranular corrosion. This alloy, now known as alloy 20Cb-3, has a typical composition of Fe-34Ni-20Cr-3.3Cu-2.5Mo. Corrosion resistance of alloy 20Cb-3 is similar to that of CN-7M. Figure 9 shows an isocorrosion diagram for alloy 20Cb-3.

Iron-Base Ni-Cr-Mo-Cu Alloys. Figure 10 shows an isocorrosion diagram for a 25Ni-20Cr-4.5Mo-1.5Cu alloy such as alloy 904L (UNS

N08904). The copper addition of 1.5% makes the alloy suitable for the entire concentration range at ambient temperature. Other alloys in this family (UNS N08926 and N031254) with less copper and more molybdenum have similar resistance.

Higher Chromium Fe-Ni-Mo Alloys

Alloy 31 (UNS N08031), also known as Nicrofer 3127 hMo, was developed in the late 1980s and was designed for increased temperature limits in H_2SO_4 over the 20 to 80% composition range versus other stainless steels and nickel-base alloys. The typical composition of this alloy is 32Fe-31Ni-27Cr-6.5Mo-1.2Cu. It shows useful resistance in 0 to 60% acid at 85 °C (185 °F) and in 60 to 80% acid at 70 °C (160 °F). Its short-term isocorrosion diagram is shown in Fig. 11 (Ref 27). Similar alloys with less chromium (N08026) or less molybdenum (N08028) have slightly less resistance.

High Cr-Fe-Ni Alloy

Alloy 33 (R20033) was specifically designed for high-temperature, concentrated sulfuric acid in 1995. The typical composition is 33Cr-32Fe-31Ni-1.6Mo-0.4N. The high chromium and low molybdenum content provides excellent resistance in hot concentrated oxidizing acid. Corrosion data summarizing alloy 33 versus other alloys is shown in Tables 3 and 4 (Ref 28, 29).

Nickel-Base Alloys

The nickel-base alloys have good resistance to corrosion in H_2SO_4 up to 95% concentration because of their high alloy content. Frequently, low corrosion rates occur in both the active and passive corrosion states. Thus, reliable corrosion behavior is achieved over a wide range of concentrations, temperatures, and impurity levels. Extensive discussion, data, and references are given in Ref 15 and 30 to 32.

Nickel-Base Fe-Cr-Mo-Cu Alloy. Alloy 825 (N08825) has useful resistance to H_2SO_4 up to 40% concentration and in concentrated acid (Fig. 12). The higher nickel content of this alloy versus the 20-type alloys offers slightly improved corrosion resistance at high temperatures in low and high concentrations of H_2SO_4 .

Nickel-Base Cr-Fe-Mo-Cu Alloys. The nickel-base "G" alloys (G, G-3, and G-30) are modifications of the now obsolete Hastelloy F. A typical composition of G-30 (N06030) is 43Ni-30Cr-15Fe-5.5Mo-5Co-2.7W-1.7Cu. Alloys G-3 and G-30 are modified versions of alloy G

with the same general corrosion resistance. It was modified to resist formation of grain-boundary precipitates during prolonged heating, such as stress relief. These alloys are promoted for their resistance to halide-contaminated H_2SO_4 environments. Figures 13 and 14 show isocorrosion diagrams for alloy G.

Nickel-Copper Alloys. Alloy 400 is used for handling H_2SO_4 under reducing conditions. Thus, this alloy offers an alternative to stainless steels and other alloys exhibiting active-passive behavior when H_2SO_4 solutions are not oxidizing, such as deaerated dilute acid. Alloy 400 exhibits reasonably low corrosion rates in air-free H_2SO_4 up to 85% concentration at 30 °C (86 °F) and up to 60% concentration at 95 °C (203 °F).

Fig. 14 Isocorrosion diagram for alloy G in H_2SO_4 solutions contaminated with Cl^- ion. Source: Ref 15

Nickel-Base Molybdenum-Chromium Alloys. The nickel-base "C" alloys, containing about 16% Mo and 16 to 22% Cr are available in wrought (alloy C-276) (UNS N10276) and cast forms (ASTM A494, grades CW-12MW, CW-6M, CW-2M, CX2MW). In general, the corrosion resistance is excellent (Fig. 15, 16). At room temperature, the corrosion rate for all concentrations is less than 0.1 mm/yr (4.0 mils/yr). Other wrought alloys in the "C" family with similar resistance are N06686, N06059, and N06022. Because of the higher chromium content, these "C" alloys are more resistant to H_2SO_4 containing oxidizing contaminants than alloy 400 or the "B" alloys. Another material in this group, with about 9% Mo, is alloy 625 (Fig. 17) (Ref 30).

Fig. 15 Isocorrosion diagram for alloy C-276 in H_2SO_4 . Source: Ref 15

Fig. 17 Isocorrosion diagram for alloy 625 in H_2SO_4 . Source: Ref 30

Nickel-Base Molybdenum Alloys. The “B” alloys contain about 28% Mo and 1% Cr and are available in the cast and wrought forms. The corrosion resistance of these alloys is excellent in pure H_2SO_4 over a wide range of temperatures and concentrations. However, oxidizing contaminants, such as Fe^{3+} ions, increase corrosion rates considerably and have caused premature failure. Chlorides also increase corrosion rates. Alloys B-2 (N10665) and B-3 (N10675) are the wrought materials in this alloy group (Fig. 18). The cast version with similar corrosion resistance is ASTM A494, grade N-12MV.

Nickel-base Cr-Fe-Co-Si alloys were developed specifically for hot concentrated H_2SO_4 pump and valve applications. Proprietary alloy 55 is one such cast alloy (Fig. 19). Figure 20 shows the effect of temperature in 98% H_2SO_4 as determined by laboratory tests. Alloy 66 is a ductile cast alloy that can also be made in the wrought form. Both forms have useful corrosion

Fig. 18 Isocorrosion diagram for alloy B-2 in H_2SO_4 . Source: Ref 15

Fig. 19 Isocorrosion diagram for alloy 55 in H_2SO_4 . Source: Ref 15

Fig. 20 Corrosion of alloy 55 in 98% H_2SO_4 . Source: Ref 15

resistance in the 0 to 60% and 80 to 99% ranges, but performance is erratic in the 60 to 80% range (Fig. 21) for alloy 66.

Nickel-base Cr-Mo-Cu alloys are proprietary alloys designed to resist H_2SO_4 concentrations to 98% at temperatures to 100 °C (212 °F). Illium 98 is a weldable, machinable cast alloy. Illium B, also a cast alloy, is a version of 98 that has been modified for enhanced corrosion resistance; however, Illium B is not easily welded (Fig. 22).

Nickel-Base Chromium-Silicon Alloy. The D-205 (Haynes International) nickel-base alloy was first marketed in the 1990s to provide outstanding resistance to high-temperature concentrated sulfuric acid with the added capability of fabrication in thin sections and complex shapes. Its composition is 65Ni-20Cr-6Fe-5Si-2.5Mo-2Cu-0.03C. Its advantage over the high-silicon stainless steel is formability in thin sections. It is ideal for plate and frame heat exchangers. Corrosion resistance at less than <0.1 mm/yr (<4 mils/yr) is reported for 93% acid at 90 °C (195 °F) and for 98 to 99% acid at 130 °C (265 °F) (Ref 32). It is also reported to have excellent resistance to concentrated acid with oxidizing impurities.

Other Metals and Alloys

Zirconium. The corrosion resistance of zirconium (R60702) in H_2SO_4 depends on the

Fig. 21 Corrosion rates of alloy 66 in H_2SO_4 solutions of 100 °C (212 °F). Source: Ref 15

Fig. 22 Isocorrosion diagram for Illium B in H_2SO_4 . Source: Ref 15

formation of a highly ordered and corrosion-resistant passive film. However, as temperature and/or concentration increases, the transpassive (breakdown) potential decreases, and there is less tolerance for oxidizing agents, such as Fe^{3+} , Cu^{2+} , and nitrate (NO_3^-) ions. Thus, zirconium has excellent resistance to H_2SO_4 up to 50% concentration at temperatures to boiling and above. From 50 to 65% concentration, resistance is generally excellent at elevated temperatures, but the passive film is a less effective barrier. Experience has shown that welding and the presence of oxidizing species in more than 50% H_2SO_4 can encourage selective attack. In concentrated H_2SO_4 above 70%, the corrosion rate of zirconium increases rapidly with increasing concentration (Ref 33). Zirconium is generally not used above 55% concentration in the welded condition unless it has been heat treated to maximize corrosion resistance (Ref 34). Figure 23 shows the corrosion rates of zirconium as a function of temperature and H_2SO_4 concentration. Control of tin content helps control harmful second-phase particles and improves corrosion resistance in the welded condition (Ref 35). Stress cracking has been reported in the base alloy in the 64 to 69% concentration range (Ref 36).

Tantalum and Ta-2.5W alloys have resistance to H_2SO_4 over the entire range of concentration and temperature except for very strong and exceptionally hot conditions. Figure 24 shows the corrosion rates of tantalum in 98% acid and oleum. A common use is for reboilers used for the concentration of H_2SO_4 in the 70% concentration range. Recent long-term testing has shown that the Ta-2.5W alloy performs at least as well as unalloyed tantalum in hot concentrated sulfuric acid service. In addition, the Ta-2.5W alloy shows clear superiority in hot concentrated acid containing oxidizing impurities such as nitrates (Ref 37, 38).

Unalloyed titanium is rapidly attacked by all concentrations of H_2SO_4 except very dilute

Fig. 23 Corrosion of zirconium by H_2SO_4 as a function of temperature and acid concentration. Source: Ref 33, 34

solutions. Impurities in the form of oxidizing agents may act as inhibitors; for example, titanium resists 0 to 50% concentrations of H_2SO_4 saturated with chlorine (Ref 39, 40). Titanium has also been used in the H_2SO_4 leaching of nickel ores. Resistance is attributed to the presence of heavy-metal oxidizing agents, such as Fe^{3+} and Cu^{2+} ions (Ref 41, 42).

Lead resists H_2SO_4 , but its protective sulfate film is increasingly soluble above 90% concentration. The film is easily damaged by erosion or abrasion even at low velocities, with the rate of attack increasing rapidly with concentration. Lead is useful as a pan material to catch acid drippings. It also has been used as a membrane behind brick in H_2SO_4 concentrating units and scrubbing towers.

Copper and copper-base alloys are not widely used in relatively pure H_2SO_4 because of the drastic effect of oxidizing conditions. The resultant Cu^{2+} ions also cause autocatalytic corrosion. Brass is not often used because of the potential for dezincification. Bronzes have the greatest applicability, with the normal copper-tin bronzes showing acceptable service below 60% concentration at 79 °C (174 °F). The silicon bronzes extend the suitable range to about 70% concentration. The aluminum bronzes have resistance approaching that of alloy 400; however, dealuminification can be a problem,

particularly with alloys containing more than 8% Al (Ref 4).

Nonmetals

Nonmetallic materials of construction have wide application in H_2SO_4 . Most of these materials have good corrosion resistance to the pure acid, particularly in dilute concentrations. They are relatively unaffected by most inorganic contaminants, except for strongly oxidizing agents such as HNO_3 , peroxides, and dichromates. Materials selection and design are normally done in collaboration with knowledgeable materials suppliers and fabricators.

Brick linings have been used for the most severe H_2SO_4 conditions. Under most conditions, acid-resistant fire clay brick can be used. Bricks and ceramics can be attacked at extremely high temperatures, and performance should be monitored or testing done. At concentrations below 70% lead, plastic, or elastomeric corrosion-resistant membranes are required behind the brick. The brick serves as a thermal and abrasion barrier. At higher concentrations, brick can be used directly against steel, although polytetrafluoroethylene (PTFE) or mortar barriers are often used. For moderate concentrations and temperatures, plastic mortars, such as furans and phenolics, are used. For high temperatures and concentrations, the silicate cements are required. Potassium silicate cement is now preferred instead of sodium silicate because its sulfate salt does not hydrate. Mortars based on pure colloidal silica are also available for extreme conditions.

Polyvinyl chloride (PVC) has excellent resistance to H_2SO_4 up to at least 93% concentration at ambient temperature. Chlorinated PVC resists slightly higher concentrations and temperatures. These materials have been used for piping, but are not popular for longer runs, because they have high coefficients of expansion and require essentially continuous support. Some companies prohibit the use of solid non-reinforced plastic piping because of the potential for breakage.

Lined Pipe. Polyvinylidene chloride (PVDC), polypropylene (PP), polyvinylidene fluoride (PVDF), PTFE, and perfluoroalkoxy (PFA) are

used for linings in pipe for handling H_2SO_4 . The temperature range of chemical resistance is shown in Table 5. At elevated temperature, performance is also limited by mechanical properties and permeation.

Polyethylene is reported to be resistant to attack by H_2SO_4 up to 98% concentration at ambient temperature for short duration service. Polyethylene is widely used in laboratories for beakers, bottles, and so on, which do not require heating over direct flames. The use of polyethylene equipment for industrial handling of H_2SO_4 has mixed reviews. Tanks constructed of molded, seamless, high-density, cross-linked polyethylene (XLPE) have been used to store relatively small volumes of concentrated H_2SO_4 up to 96%. However, failures due to acid attack have been reported, and some vendors restrict life guarantees for high concentrations. Some operators limit the use of solid nonreinforced plastic tankage due to performance concerns.

Fluoroplastics. Fully fluorinated plastics, such as PTFE, fluorinated ethylene propylene (FEP), and PFA, are unattacked by H_2SO_4 and oleum at all concentrations. Other fluoroplastics, including PVDF, ethylene-chlorotrifluoroethylene (ECTFE), and ethylene-tetrafluoroethylene (ETFE), are resistant to acid up to 98% concentration, but have less resistance to oleum and SO_3 . Table 6 lists temperature limitations for chemical attack. At elevated temperature, fluoroplastic linings are limited by mechanical properties, permeation, and adhesives.

Fluoroplastics are being increasingly used for H_2SO_4 applications, such as linings in pumps and valves. Fiberglass-backed sheet linings of FEP, PTFE, and PVDF permit fabrication of large components, such as tanks. Rotomolding and dispersion powder linings of PVDF, ECTFE, ETFE, and PFA, with or without fiber reinforcement, are applied to a broad range of steel equipment (Ref 45). Equipment size is limited only by available ovens.

Fig. 24 Corrosion of tantalum in 98% H_2SO_4 and in oleum

Table 5 Chemical resistance of lined-pipe systems to sulfuric acid

PTFE, polytetrafluoroethylene; PFA, perfluoroalkoxy; ECTFE, ethylene chlorotrifluoroethylene; FEP, fluorinated ethylene propylene copolymer resin with TFE; ETFE, modified ethylene-tetrafluoroethylene; PVDF, polyvinylidene fluoride. (a) Above 110 °C (230 °F), service as a lining may be limited by permeation, mechanical properties, thermal expansion, and adhesives. (b) PVDF and ETFE may be attacked by free SO_3 present at concentrations slightly higher than 98%. Source: Ref 43, 44

Polyester Resins. Polyester and vinyl-ester resins, normally used to form a fiberglass-reinforced plastic (FRP) laminate, are available to resist dilute H_2SO_4 at 93 °C (200 °F). At 50 to 70% concentration, FRP tanks and vessels with proper resins can be safely used to 65 °C (150 °F) and can even find application in special cases where the temperature approaches 80 °C (175 °F). At 70 to 75% acid, the temperature should be restricted to less than 40 °C (104 °F). Above 80% concentration, most polyester and vinyl-ester resins are rapidly degraded even at ambient temperatures.

Carbon and Impervious Graphite. Impervious graphite has excellent corrosion resistance to all but highly oxidizing concentrations of H_2SO_4 . Impervious graphite coolers are used in 93% H_2SO_4 (Ref 46). Phenolic and PTFE impregnants are readily available. Carbon is somewhat superior to graphite in the higher concentrations and is generally preferred for hot acid at concentrations above 60%. Carbon is less conductive and lacks strength and is therefore unsuitable for cooler construction. Both carbon and graphite are, of course, brittle (Ref 47, 48).

Phenolic Linings. Heat-cured phenolic linings on steel are often used to prevent iron contamination in 93% H_2SO_4 and have reasonable life in 98% H_2SO_4 at ambient temperature. These thin-film linings should not be used for concentrations below 70% because of rapid corrosion of exposed steel substrate at expected pinholes.

Butyl rubber and neoprene exhibit good resistance to 50% H_2SO_4 at modest temperatures and will resist 75% acid under ambient conditions.

Glass and glass-lined equipment is widely used in H_2SO_4 service. For severe H_2SO_4 applications, glass-lined steel is a popular material of construction.

NITRIC ACID (HNO_3) is one of the most widely used acids in the chemical processing industry. In the United States alone, there are more than 65 HNO_3 manufacturing facilities with a total capacity of more than 11 million tons/yr. Plants range in size from 6,000 to 700,000 tons/yr. Approximately 70% of all HNO_3 produced is used in the manufacturing of ammonium nitrate that is then used in fertilizers. Nitric acid is also a key component in the manufacturing of adipic acid and terephthalic acid. Other uses include the production of industrial explosives such as nitroglycerin and trinitrotoluene (TNT), dyes, plastics, synthetic fibers, and in metal pickling and the recovery of uranium.

The basic HNO_3 process involves the oxidation of a preheated air-ammonia mixture in the presence of a catalyst at approximately 925 °C (1700 °F). The resulting gas, consisting of various oxides of nitrogen, water vapor, and air, passes through heat-recovery equipment, a cooler condenser, and an absorption tower. Condensed acid in the concentration range 60 to 65% is drawn from the cooler condenser and absorption tower. Uncondensed vapor and air are recirculated. The higher the pressure in the condensing and absorption stage, the greater the process efficiency. This process can be performed at one or multiple pressures. Newer processes typically operate at a low and high pressure to favor the reactions. The azeotrope of HNO_3 and water at atmospheric pressure is 67% HNO_3 . Higher concentrations of acid in the range 90 to 100% are produced by extractive distillation using concentrated sulfuric acid as a dehydrating agent. The terminology used to describe HNO_3 mixtures that are generally accepted is shown in Table 1 (Ref 1).

Nitric acid is a strongly oxidizing acid that is aggressively corrosive to many metals. Acid temperature and concentration affect corrosion rate as does the composition of the alloy exposed to it. General attack, crevice attack, and intergranular attack are common in HNO_3 . Stress-corrosion cracking (SCC) can occur in zirconium alloys exposed to hot >70% HNO_3 . Velocity,

aeration, and the presence of impurities such as chlorine and fluorine in the acid all affect corrosion rate. Stainless steels, chromium-containing alloys, aluminum, and—to a lesser degree—titanium and zirconium alloys are useful in HNO_3 . Carbon steel and copper alloys are not. The materials of construction used for handling HNO_3 will depend on the application and the type of equipment, acid concentration, and temperature. Table 2 provides a summary of the common materials used at various acid concentration ranges and temperatures (Ref 1).

Carbon and Alloy Steels

The ferrous alloys, consisting of iron plus carbon or other elements in small amounts, are passivated upon immersion in concentrated HNO_3 , but the protective film is so easily damaged that they are not useful in HNO_3 applications. In practice, both wrought and cast ferrous alloys corrode very rapidly. The application of anodic protection to the corrosion of carbon steel has been studied and found to be effective in reducing the corrosion rate in various strengths of HNO_3 (Ref 2). The technique, however, has not found any industrial applications.

Stainless Steels

The presence of many of the common alloying elements in stainless steels can be either

detrimental or dramatically beneficial to the resistance of an alloy in HNO_3 . Chromium is considered the most beneficial element in providing corrosion resistance of stainless steels in HNO_3 . If carbon, phosphorus, sulfur, titanium, or molybdenum is present, the general corrosion resistance of the alloy system will decrease with increasing concentration of that element. These elements either form separate phases that are susceptible to selective attack by HNO_3 or tie up chromium and increase the sensitivity of the alloy to selective attack at the grain boundaries. Addition of silicon to stainless steels increases their corrosion resistance at high acid concentrations.

The most widely used grade of stainless steels for HNO_3 is the low-carbon grade UNS S30403 (304L) and to a lesser extent the stabilized austenitic grades UNS S32100 (321) and UNS S34700 (347). The isocorrosion diagram for type 304 stainless steel in HNO_3 is shown in Fig. 1. This diagram shows the effect of temperature and HNO_3 concentration on the corrosion of type 304 stainless steel. Increasing either or both raises the corrosion rate; nevertheless, there is a large useful area extending from 0 to 90% concentration and up to the boiling point below 50% concentration in which the predicted corrosion rate is less than 0.13 mm/yr (5 mils/yr) (Ref 3). The corrosion of austenitic stainless steels in HNO_3 is accompanied by the formation of hexavalent chromium (Cr^{6+}), a complex chromium compound that increases the corrosivity of HNO_3 solutions. The effect of Cr^{6+} buildup is shown in Fig. 2 to be clearly detrimental (Ref 4).

Table 1 Nitric acid nomenclature

Name	Composition, wt%
Weak or tower acid	50–65% (nominally 57%)
Commercial 42° baumé	67% (American Chemical Society, ACS, grade)
Chemically pure (CP) or reagent grade 43° baumé	70.3%
Strong or concentrated acid	95–99%
White fuming nitric acid (WFNA)	95–99% <0.5% NO_x
Red fuming nitric acid (RFNA)	95–99% + NO_x 6–30%
Inhibited RFNA	98% plus 15% H_2SO_4

The problem of intergranular corrosion in weldments of the high-carbon UNS S30400 (304) has been minimized by the use of type 304L grades. Modern steelmaking practice makes it possible to make steels with precise element control resulting in the 300 series stainless steels having elements such as chromium produced to the low end of the specification. Reduction in the chromium level may result in increased corrosion rate of the stainless steels.

The difference in the corrosion behavior between type 304L and 316L in HNO₃ is often not substantial and can sometimes be attributed to differences in chromium content rather than the presence or absence of molybdenum. Since type 304L is less expensive than type 316L, it is preferred for HNO₃ applications. The exception would be if substantial levels of impurities are present in the acid that would benefit from type 316L molybdenum grade. The molybdenum grade might also be better in heat-exchanger

**Fig. 2** Effect of hexavalent Cr⁶⁺ contamination on the corrosion rate of type 304 stainless steel in HNO₃. Source: Ref 4

applications where the resistance to pitting on the water side would be beneficial. Welds of type 304L welded with E308L, in the “as welded” condition and welded and sensitized condition show no preferential attack in boiling HNO₃. Welded and sensitized stabilized grades, such as types 347 and 321, can suffer on occasion from “knife-line” attack in boiling HNO₃. Sensitized

welds in type 316L are subject to accelerated attack in boiling HNO_3 (Ref 1).

Nitric Acid Grade (NAG) Wrought Stainless Steels. In HNO_3 up to 67% concentration at elevated temperature, type 304L stainless steels are in the transition region between passive and transpassive behavior and can therefore lead to intergranular corrosion at heat-affected zones (HAZ) near welds. To further reduce intergranular corrosion, type 304L stainless steels can be produced using electrosag refining techniques with extremely low carbon, silicon, phosphorous, and sulfur levels with optimized microstructures. These stainless steels are referred to as types 304 Special or 304 NAG (UNS S30403 NAG). Type 316L NAG is also produced by control of composition to minimize second-phase formation (ferrite and sigma), together with low residuals of silicon, phosphorous, and sulfur.

The beneficial effects of increasing chromium additions to an alloy system exposed to HNO_3 have been universally accepted. Type 310L (UNS S31050), an austenitic alloy that contains nominally 25% Cr, 20% Ni, and very low carbon (0.02%) as well as being low in other interstitial elements offers significant advantages over type 304L at high temperatures and is often used for condensers in concentrating of the acid. The excellent performance of type 310L depends on obtaining a fine-grained microstructure (ASTM 4 to 6) and ensuring that it is free of carbide precipitation (Ref 1).

The other alloying element that improves the corrosion resistance of stainless steels in HNO_3 environments is silicon. With levels above 2% Si in the alloy, a thick silica layer forms on top of the normal chromium oxide film present on stainless steels. The two most common austenitic stainless steel alloys containing silicon are A610 (UNS S30600), which contains nominally 18% Cr, 15% Ni, and 4% Si, and A611 (UNS S30601), which contains nominally 18% Cr, 17% Ni, and 5.3% Si. Both these alloys have excellent resistance to highly concentrated HNO_3 ; however, they are less corrosion resistant than types 304L and 310L at lower concentration. Figure 3 shows the corrosion rate of 304L, 310L (2521LC), and A610 (1815LC Si) in boiling HNO_3 (Ref 5).

Fig. 3 Corrosion rates of 304L, 310L (2521LC), and A610 (1815LC Si) in boiling HNO_3 . Source: Ref 5

Vapor/Liquid. Most corrosion data are derived from laboratory tests made in the liquid phase; however, in actual plant equipment there is often a vapor space above the liquid acid where acid vapor composition may vary from the bulk liquid. This acid vapor may condense on the equipment inner surface and be more or less corrosive than the bulk liquid. Strong acid vapors will generally be more corrosive than the bulk liquid. Vapor-phase corrosion is a potential problem for stainless steel tanks handling concentrations greater than 90%. In this case, the vapors contain much stronger HNO_3 than the liquid because of the higher volatility of HNO_3 over strong acid, and the condensate can be corrosive to these stainless steels. Vents on high HNO_3 concentration aluminum storage tanks can cause accelerated corrosion in adjacent areas because atmospheric moisture enters the tank and dilutes the acid into the range where it is corrosive to the aluminum.

Cast Stainless Steels. The equivalent cast version of types 304 and 304L, ACI CF-8 (J92600) and ACI CF-3 (J92500), respectively, have approximately the same corrosion resistance to HNO_3 as the wrought alloys. The molybdenum-bearing cast ACI grades CF-8M (J92900) and CF-3M (J92800) are more available and are used for pumps and valves in HNO_3 service. The cast version of alloy 20, ACI CN-7M (N08007), is also commonly used in pumps and valves in HNO_3 service at elevated temperatures up to 70% concentration. Cast low-carbon, high-silicon stainless steels have been developed for HNO_3 service based on 20% Cr and 13% Ni with varying amounts of silicon up to 6.5%. A cast version of S30600 (J93900), containing 21% Cr, 16% Ni, and 5% Si, known as Durcomet 5, is used for pumps and valves in concentrated HNO_3 service. Silicon cast irons containing 14.5% Si (e.g., UNS F47003) exhibit excellent corrosion resistance to HNO_3 above 45% at temperatures up to the boiling point. The resistance increases with increasing concentration. Corrosion rate becomes nil in strong acid at high temperatures. The corrosion resistance can be attributed to the formation of an adherent siliceous film (Ref 1).

Other Austenitic Alloys

Because of the generally good performance of the stainless steels with a wide range of acid concentrations and temperatures, the more costly and more highly alloyed stainless steels and Ni-Cr-Mo alloys are not widely used in the handling of straight HNO_3 solutions. These latter materials are more likely to be used with mixtures of HNO_3 with other acids, such as sulfuric (H_2SO_4) or hydrofluoric (HF) acids, or where some chlorides may be present to cause SCC or pitting of the austenitic stainless steels. Some of the alloys with high chromium content that have been used in various HNO_3 applications include alloy 20 (N08020), G30 (N06030), alloy

33 (R20033), alloy 28 (N08028), alloy 22 (N06022), and alloy 625 (N06625). The nickel-base alloys that are essentially chromium-free, such as alloys 200 (N02200), 400 (N04400), B2 (N10665), and their variants, suffer immediate attack in HNO_3 .

Aluminum Alloys

All aluminum alloys, welded and unwelded, have good resistance to uninhibited fuming HNO_3 (red and white) up to 50 °C (122 °F). Above this temperature, most aluminum alloys exhibit knife-line attack adjacent to the welds in uninhibited acid. Above 50 °C (122 °F), the depth of knife-line attack increased markedly with temperature. One exception was in the case of a fusion-welded 1060 (UNS A91060) alloy in which no knife-line attack was observed even at temperatures as high as 70 °C (160 °F). In inhibited fuming HNO_3 containing at least 0.1% HF, no knife-line attack has been observed for any commercial aluminum alloy or weldment even at 70 °C (160 °F) (Ref 6).

Aluminum alloys are good only for very high concentrations, for example, greater than 80% at room temperature and greater than 93% at 43 °C (110 °F). Aluminum alloys commonly used are UNS A91100, A93003, A95052, and A95454. The first two alloys must be welded with A91100 or A91060 rod, the second two with A95356. Welds made with A91100 may suffer intergranular attack if the iron content is too high, and the high-silicon rods, for example, A94043, are subject to accelerated preferential attack. UNS A91100 is a commercial grade of aluminum containing 98.85% Al. The material, although structurally weak, has excellent resistance to corrosion in 95%+ acid at ambient temperatures. The isocorrosion diagram for A 91100 is shown in Fig. 4 (Ref 3). The alloy should be fusion welded using only matching 1100 filler metal to maintain the corrosion resistance. UNS A93003 is a commercial grade of aluminum containing 1.25% Si, 0.7% Mn, and 0.2% Fe. This alloy offers improved strength properties over A91100 but at some loss of corrosion resistance. This alloy can replace A91100 when a little more strength is required and should be fusion welded using 1100 filler metal to avoid weld corrosion. UNS A95454 is an aluminum alloy containing 2.7% Mg for additional strength. Its corrosion resistance in HNO_3 is slightly reduced from A91100 or A93003. Its primary application is found in rail and highway equipment tankage. UNS A95454 should be fusion welded using A95356 filler metal. UNS A95056 is an alloy containing 5% Mg that is still stronger than A95454 and thus offers a higher-strength alternative at some loss of corrosion resistance. Primary usage is in transportation tankage. For fusion welds, filler metal A95356 should be used. Other aluminum alloys of the 5000 series designation may also be used in HNO_3 applications. Their corrosion resistance

Fig. 4 Isocorrosion diagram for aluminum alloy A91100 in HNO₃. Source: Ref 3

Fig. 5 Corrosion of titanium alloys in boiling HNO₃. Acid solutions were refreshed every 24 h. Source: Ref 7

should be comparable to the specific alloys mentioned, but there is no test data. Alloy A96061 should not be used in HNO₃, as erratic corrosion has been observed.

Titanium

Unalloyed titanium has been extensively utilized for handling and producing HNO₃ in applications where stainless steels have exhibited significant uniform or intergranular attack. Titanium offers excellent resistance over the full concentration range at subboiling temperatures. The corrosion resistance up to 70% concentration at 70 °C (160 °F) is below 0.04 mm/yr (1.6 mils/yr). As temperature exceeds 80 °C (175 °F), however, the corrosion resistance becomes highly dependent on acid purity. The corrosion resistance of titanium in boiling HNO₃

over a range of strengths is shown in Fig. 5. Ti grade 12 (R53400), which contains molybdenum and nickel, is a higher-strength alloy with improved corrosion resistance in HNO₃ (Ref 7).

In hot, very pure solutions or vapor condensates of HNO₃, significant general corrosion (and trickling acid condensate attack) may occur in the 20 to 70 wt% range. Under marginal high-temperature conditions, higher-purity unalloyed grades of titanium (i.e., grade 1) are preferred for curtailing accelerated corrosion of weldments. In hot pure acid, the resistance of titanium improves dramatically when there are trace amounts of oxidizing ions, in particular, Ti⁴⁺. That is, the initial high corrosion rate of titanium will quickly inhibit its corrosion as illustrated in Table 3 (Ref 8). Often, oxidizing impurities, such as Si⁴⁺, Fe³⁺, Cr⁶⁺, and Pt²⁺, are present in the HNO₃ stream. These impurities are harmful to stainless steels but are very beneficial to

Table 3 Effect of added Ti⁴⁺ on the corrosion of unalloyed titanium

Ti ion Added, mg/L	Corrosion rate			
	for 40% HNO ₃		for 68% HNO ₃

80	0.02	0.79	0.01	0.40

Source: Ref 8

Fig. 6 Isocorrosion curve for zirconium in HNO₃. Source: Ref 8

titanium. Consequently, titanium becomes more suitable than stainless steels in applications such as reactors, stripper reboiler loops, spent HNO₃ recovery systems, and evaporator reboilers. For cooler condenser applications, titanium is vulnerable to corrosion if significant condensation occurs. Similarly, titanium may be attacked in the vapor phase of strong HNO₃.

Titanium alloys have good corrosion resistance in white fuming HNO₃. However, pyrophoric reactions may occur when they are exposed to red fuming HNO₃ or to nitrogen tetroxide gas. The attack is intergranular and results in breaking down the surface into fine particles. Fine titanium particles are highly reactive. The critical variables are the nitrogen dioxide and water contents of the acid. Fuming HNO₃, containing less than 2% water or more than 6% nitrogen dioxide, may cause this pyrophoric reaction to occur. Both water and nitrogen monoxide are effective inhibitors for this reaction, but increasing oxygen and nitrogen dioxide are detrimental in this situation (Ref 7).

Zirconium Alloys

The excellent corrosion resistance of zirconium in HNO₃ has been recognized for more than 30 years. Zirconium alloys have excellent corrosion resistance under the most severe conditions of concentration and temperature (Fig. 6). The corrosion resistance of zirconium is

less than 0.13 mm/yr (5 mils/yr) below 250 °C (480 °F) up to 70% concentration and below 150 °C (300 °F) between 70 to 90% concentration. Zirconium alloys are not normally used above 90% acid concentration.

Zirconium is normally susceptible to pitting in acidic oxidizing chloride solutions. However, nitrate ion is an inhibitor for the pitting of zirconium because of its passivating power. The minimum $[\text{NO}_3^-]/[\text{Cl}^-]$ molar ratio required to inhibit pitting of zirconium is between 1 and 5 (Ref 9–11). Results of tests indicate that the resistance of zirconium is not degraded in up to 70% HNO_3 with the addition of 1% ferric chloride, 1% sodium chloride, 1% seawater, 1% ferric ion, or 1% stainless steel at 204 °C (399 °F). Still, the presence of an appreciable amount of hydrochloric acid (HCl) should be avoided since zirconium is not resistant to aqua regia.

In the production of HNO_3 , ammonia is oxidized with air over platinum catalysts. The resulting nitric oxide (NO) is further oxidized into nitrogen dioxide (NO_2), then absorbed in water to form HNO_3 . Acid of up to 70% concentration is produced at temperatures up to 204 °C (399 °F) by the process. Zirconium is one of very few materials that are suitable for this process when the temperature is near the high end.

The polarization curves of zirconium in HNO_3 are shown in Fig. 7. Zirconium has the passive-to-active transition similar to that which occurs in H_2SO_4 . However, corrosion potentials are very noble because of the oxidizing nature of HNO_3 . Stress-corrosion cracking occurs in zirconium when it is above the transition region between passivity and transpassivity (Ref 12, 13). The relationship between HNO_3 concentration, potential, and susceptibility to SCC is shown in Fig. 8 (Ref 1, 14). The addition of titanium to zirconium increases the transition potential and thus resistance to SCC. Stress-corrosion cracking of zirconium equipment can be reduced by a stress-relieving treatment.

Additional concerns include the accumulation of chlorine gas in the vapor phase and the

presence of fluorides. Chlorine gas may be generated by the oxidation of chlorides by HNO_3 . Areas that can trap chlorine gas should be avoided for zirconium equipment when chlorides are present in HNO_3 . The corrosion of fluoride-containing HNO_3 solutions can be controlled by adding an inhibitor, such as zirconium sponge or zirconium nitrate, to convert fluoride ions into noncorrosive complex ions (Ref 8).

Niobium and Tantalum

Niobium and tantalum are among the metals most corrosion resistant to HNO_3 . They exhibit resistance in the acid at all concentrations to temperatures as high as 250 °C (480 °F). The presence of chloride impurities does not degrade their resistance. They are not vulnerable to pyrophoric reaction in red fuming HNO_3 either.

Nevertheless, there are differences among these metals. Tantalum can tolerate more H_2SO_4 contamination than niobium can. This is an important consideration when H_2SO_4 is used as the dehydrating agent in making concentrated HNO_3 . On the other hand, niobium can tolerate more fluoride contamination than tantalum can (Ref 8).

Nonmetallic Materials

Plastics. The use of plastics, mainly fluoroplastic materials, is confined to linings for pipe and vessels, rather than as solid construction, because of the hazardous nature of HNO_3 (see Table 2). Polytetrafluorethylene (PTFE) will resist up to 70% acid to about 230 °C (450 °F), but a limit of about 25 °C (75 °F) is suggested above that concentration, primarily because the vapors tend to permeate the plastic. Fluorinated ethylene propylene (FEP) will tolerate up to 100% acid to 200 °C (390 °F), while polyvinylidene fluoride (PVDF) is recommended to about 50% concentration to 52 °C (125 °F) (Ref 1).

Fig. 7 Anodic polarization curves for unalloyed zirconium in near-boiling HNO_3 as a function of concentration (wt%). Applied potential is given in volts versus the saturated calomel electrode (SCE). Source: Ref 8

Fig. 8 Relationship between potential and HNO_3 concentration on the susceptibility of zirconium to SCC. Source: Ref 14

The chlorinated and vinyl ester thermosetting resins have been used in combination with fluoroplastics in dual-laminate construction storage tank applications. If used without a fluoroplastic liner the vinyl ester resins have satisfactory resistance up to 20% acid to about 65 °C (150 °F) and up to 35 °C (95 °F) at 40% concentration. The vinyl ester resin is not suitable above the 40% acid concentration.

Elastomers. Elastomeric products can be successfully used as sealing components at various temperatures and concentrations of HNO_3 . Selection of the proper elastomeric material is critical for ensuring long-term, reliable service. Variations in elastomer compound formulations and cure chemistry can result in performance differences. Therefore, testing of elastomeric seals is always recommended before use. The perfluoroelastomers (FFKM) and PTFE-based elastomers are the only elastomers that are useful over a wide range of concentration and temperature. Rubber and other synthetic elastomers can be used only in very dilute HNO_3 at ambient temperatures (Ref 1). Due to the wide variation in types and quality levels of elastomers, it is important that compatibility testing is done before the appropriate selection is made.

Glass-Lined Equipment. Glass-lined steel pipe, fittings, and other equipment are available and widely used in HNO_3 (Ref 1). Glass-lined steel equipment can normally be used at any strength of HNO_3 up to the thermal limits of the glass lining. These thermal limits depend on the design of the equipment and the possibilities and extent of thermal shock, and they are aimed at keeping the glass under compressive stress. A typical maximum operation temperature is around 230 °C (450 °F). Glass-coated steel equipment is fully resistant to HNO_3 up to 70% concentration and to 125 °C (260 °F). Exposure to conditions beyond these limits will reduce the life of glass-coated equipment. Fluorides at all concentrations should be avoided since they attack the silica network, and this attack can be very severe at concentrations of HF <10 ppm. If any detectable fluorides are present, attack is likely to be accelerated. Glass-lined reactors are used by all large chemical companies. In some cases they are being used with highly concentrated HNO_3 with reaction temperatures up to 160 °C (320 °F).

Corrosion by Organic Acids

Revised by L.A. Scribner, Becht Engineering

ORGANIC ACIDS represent a key group of industrial chemicals. They are often used in their pure form, and they are used as an intermediate in a wide variety of chemical reactions to make products ranging from polyester clothing to amino acids used in vitamins. Acetic acid is synthetically produced in the largest volume of all of the carboxylic or organic acids and is best known by the general public as the weak aqueous solution, "vinegar." The simple, straight chain aliphatic acids are discussed in this article. They are often called "fatty acids" because those containing an even number of carbon atoms (four or greater) exist in a combined form with glycerol as fats and oils.

The subject of corrosion by organic acids is complicated not only by the numerous acids to be considered, but also because the acids typically are not handled as a pure chemical but as process mixtures, with inorganic acids, organic solvents, salts, and as mixtures of several organic acids (Ref 1). They are even used as solvents in chemical reactions. The corrosion of materials by organic acids is also complicated by the virtually unlimited number of possible compounds. The corrosion of metals by organic acid is often confounded by trace impurities such as oxygen and metallic salts. This article concentrates on corrosion by acetic (CH_3COOH), formic (HCOOH), and propionic ($\text{CH}_3\text{CH}_2\text{COOH}$) acids and gives some information on longer-chain organic acids.

Corrosion Characteristics

Organic acids are weak acids when compared to the common inorganic acids such as hydrochloric (HCl) or sulfuric (H_2SO_4), but still hydrolyze well enough to act as true acids toward most metals. Aliphatic organic acids are usually considered to be slightly reducing. They are often handled in copper, which does not directly displace hydrogen from acids. The 400-series stainless steels exhibit borderline passivity and thus are seldom selected, whereas the 300-series stainless steels are the materials of choice. The grades in the 300 series of stainless steels require oxidizing conditions to maintain their passivity, especially at high temperatures. The

reversal of corrosion resistance as the environment changes from oxidizing to reducing characteristics makes contaminants extremely important because they tend to shift the oxidizing capacity of the acid mixture. Aeration (i.e., dissolved oxygen or DO), ferric ions, peracids, or peroxides will cause rapid attack of copper and copper alloys, while the presence of chlorides, which are reducing, can have disastrous effects on stainless steels. Additional information on the role of contaminants in acetic acid corrosion is provided in Ref 2. Corrosion testing can be difficult in organic acid media. Electrochemical measurements are most successful in dilute aqueous solutions of the acids because the conductance is very low in high concentrations or in solutions of nonaqueous solvents. The addition of sodium or chloride salts improves the ease in making electrochemical measurements. Reported electrochemical data obtained in strong acetic acid, acetic acid anhydride, and formic acid solutions showed active-passive behavior

of stainless steels that is consistent with field experience (Ref 3).

Figure 1, an electronically produced electrochemical stability diagram (Pourbaix diagram) of copper in acetic acid, shows results that are similar to those that have been shown by testing. The light shaded fields are those that delineate regions where copper is corroded by acetic acid. The addition of oxidizing impurities, such as ferric ions or dissolved oxygen, will serve to raise the electrochemical potential into the regions where copper forms stable soluble species and corrosion proceeds. By reference to this Pourbaix diagram, copper does not show passivity in acetic acid, but instead shows either immunity or active corrosion. One can surmise that the same electrochemical response will be found for formic and other similar organic acids.

Data obtained by simple immersion testing in the laboratory often show erroneous results unless the atmosphere is carefully controlled.

Fig. 1 Pourbaix diagram for copper in 5 M acetic acid at 80 °C (175 °F) showing the natural pH and the possible effects of oxidizing impurities. In the diagram, the darker gray area shows the region of immunity or no corrosion, the lighter gray area shows the stability of copper oxides or regions of possible passivity where low corrosion rates are expected, and the light areas show the regions of soluble copper salts and where high corrosion rates are expected. E (SHE), electrode potential measured by the standard hydrogen electrode

Without very good atmospheric control, the solution will be saturated with air at the beginning of the test, but will lose air as the temperature is increased until, at boiling conditions, almost all of the air will be removed. This situation can lead to results that vary widely, depending on the length of the test. Short tests of metals that exhibit active-passive behavior, such as the 300-grade stainless steels, can also be misleading, because the metal may remain passive for a short time and then may start to corrode actively after longer exposures.

Truly anhydrous organic acids are usually much more corrosive to stainless steels than organic acids containing even traces of water. Corrosion rates reported for glacial (concentrated) acids often reflect this effect, because the acids may be truly anhydrous or may contain small amounts of water.

Formic Acid

Formic acid is the most corrosive of the common organic acids because it is the most highly ionized, being about 10 times more ionized or acidic as acetic acid. Formic acid acts as both an organic acid and as an aldehyde and hence has reducing properties. Formic acid is somewhat unstable as the concentration approaches 100% and decomposes to carbon monoxide and water—especially when heated above 35 °C (95 °F). The following discussion is divided into metal and alloy groups used to handle formic acid.

Steel is attacked by formic acid at all concentrations and temperatures and is normally not considered suitable for formic service. Steels that have been hardened to high strengths can fail by hydrogen cracking when exposed to organic acids. Stressed 18% Ni maraging steel cracks when exposed at ambient temperatures to 10% aqueous formic acid, but does not crack in 91% formic acid, or in either glacial acid or 10% acetic acid (Ref 4).

Aluminum shows good resistance to formic acid at any concentration at ambient temperature

Fig. 2 Rate of corrosion for 1100-H14 (A91100) aluminum in aqueous reagent grade formic acid

(Fig. 2). Although pure aluminum and pure formic acid of all concentrations appears to be compatible from a corrosion viewpoint, the contamination of the acid by various impurities, such as heavy metal salts, limits the use of aluminum to shipment and storage of formic acid with a concentration greater than 95% (Ref 5).

Alloy 5086 (A95086) is an often-used grade of aluminum that is used to make storage tanks and, as shown in Fig. 3, shows acceptable corrosion rates to the higher concentrations of formic acid. Because the temperature of chemicals in shipment can get as warm as 45 °C (115 °F), testing was done at this temperature. The rate of attack on alloy 5086 decreases rapidly with increasing concentration of acid. Importantly, the acid used in the tests became turbid with aluminum salts, which lowered the acid purity. If short exposure times and/or lower temperatures during storage are forecast, or if a lower-quality formic acid that contains aluminum salts is acceptable, this aluminum can be used for the storage of 95 to 99% acid.

Copper and its alloys, except yellow brasses, which may dezincify, respond somewhat differently than aluminum on exposure to formic acid. Table 1 shows typical corrosion rates for copper (C10300) and 90Cu-10Ni copper-nickel (C70600) in various concentrations of formic acid.

Because the corrosion resistance of copper to attack by reducing acids such as formic is determined by the presence of oxidizing agents, the control of dissolved oxygen and other oxidizing species is critical. The corrosion of copper can be autocatalytic if oxygen is present since the cupric ions thus formed are in themselves oxidizing agents (Ref 6). If air or other oxidants are present, high corrosion rates are encountered; if the acid is free of air and other oxidants, copper often provides good resistance to formic acid of all concentrations to the

Fig. 3 Corrosion of 5086 (A95086) aluminum in formic acid at 45 °C (115 °F)

atmospheric boiling point and even at higher temperatures. The anomalies in the data shown in Table 1, such as the higher rate of attack in 50 and 70% formic acid, are probably caused by incomplete deaeration or cupric ion accumulation during laboratory tests.

Stainless Steels. The corrosion resistance of the various grades of stainless steels is strongly influenced by the impurities present in the acid—oxidizing or reducing. The 400-series stainless steels are usually not resistant to formic acid. However, if a PH grade were needed, type 15-7Mo (S15700) would be a candidate based on its similarity to type 316L (S31603).

Type 304 (S30400) stainless steel and its similar nonmolybdenum bearing alloys such as types 321 (S32100) and 347 (S34700) have excellent resistance to formic acid and at all concentrations, but only at ambient temperatures, and they are the preferred, low-cost material of construction for storage of the acid. However, type 304 stainless steel should not be considered for elevated-temperature use. Table 2 shows typical rates of attack on various stainless steels in several concentrations of formic acid at the atmospheric boiling temperature.

Because of intergranular corrosion, the L-grade (low-carbon) versions of stainless steels should be used in any application where the temperature exceeds ambient. Type 316L is the minimum alloy of choice of the common 300 grades of stainless steel when the temperature exceeds ambient and shows excellent resistance to formic acid in all concentrations at ambient temperatures and is resistant to at least 5% formic acid at the atmospheric boiling temperature. However, type 316 (S31600) stainless steel can be seriously attacked by intermediate strengths of formic at higher temperatures, and corrosion tests are advisable. The azeotropic concentration (78% formic acid) dripping condensate appears to cause high rates of attack on type 316 stainless, whereas those concentrations of acid above 90% are less corrosive. The control of corrosion on the 300 grades of stainless steels is a strong function of the molybdenum content. Type 317L (S31703) is the high-temperature alloy that is often

Table 1 Corrosion of copper and 90-10 copper-nickel by formic acid

90.0	0.22	8.7	0.19	7.6

selected for formic acid service because of its higher molybdenum content compared to type 316L.

Duplex Alloys. Laboratory corrosion tests of the newer grades of molybdenum-containing duplex stainless steels show corrosion resistance that exceeds that of type 317L. Alloys 2205 (S31803 and S32205) and 2507 (S32750) have corrosion rates that are lower than type 317L stainless steel. As shown in Fig. 4, alloy 2507 has outstanding resistance to hot formic acid throughout the full concentration range at 100 °C (212 °F) (Ref 7).

The 20-type alloys are more resistant to formic acid than type 316 stainless steel, and its use should be considered in higher concentrations at higher temperatures. Other alloys with chromium, nickel, and molybdenum contents higher than type 316 stainless steel, such as alloys 28 (N08028) and 904L (N08904), also show superior resistance to mixtures of formic and acetic acid and would be expected to be better in formic acid itself. Under gaskets and in other occluded areas (e.g., threaded connections), type 316L stainless steel sometimes undergoes crevice corrosion. Weld overlays of alloy 20 have proven partially successful for solving this problem. The superaustenitic alloys containing 6% Mo (e.g., alloy 6XN; N08367) should be even better than the alloy 20, which contains only 2 to 3% Mo. A 6% Mo version of the 20-type alloy, alloy 20Mo-6 (N08026), is now available.

Titanium. While titanium will resist acetic acid under almost all conditions to the boiling point, it will resist formic acid, only under strongly oxidizing conditions. Titanium exhibits borderline passivity in formic acid, and under normal conditions pure formic will corrode titanium at the boiling point in all concentrations above 10% (Ref 8). A titanium heat exchanger disappeared in less than one day when strong conditions, approaching the anhydrous state, had been encountered in a distillation system. When titanium does corrode, even slightly, hydriding of the metal occurs and loss of ductility results.

Nickel Alloys. Several of the high nickel alloys such as alloys B-2 (N10665), C-276 (N10276), and C-4 (N06455) have shown outstanding resistance to formic acid in process equipment and are reported to have very good resistance even at temperatures above the atmospheric boiling point.

Corrosion data for alloy C (N10002) are shown in Fig. 5 (Ref 9). Note that Fig. 5 also shows a zone of higher corrosion for alloy B-2. In all other areas, alloy B corroded at lower rates. Alloy B (N10001) sometimes exhibits less corrosion resistance in intermediate strengths than alloy C but, because alloy B usually costs more, it is not often selected. However, in those services that are very reducing, such as sulfuric acid catalyzed esterification reactions, alloy B is often the better choice. In services where contamination from sodium chloride or other halogens is possible, alloy B should be superior to alloy C. As is to be expected, alloy B is not

better than alloy C types when strongly oxidizing conditions prevail.

The Cr-Mo-Ni alloys are all similar to the C and B alloy types. Alloy 625 (N06625) contains only 9% Mo and should be expected to be somewhat less corrosion resistant than alloy C-276, but is so similar in resistance as to be usable in all but the most severe of services.

Other Metals. Lead is substantially non-resistant to formic acid and other organic acids. Commercially pure zirconium exhibits very good resistance to boiling formic acid with rates below 0.02 mm/yr (0.8 mil/yr), even when the acid is contaminated with metal salts or iodine. This suggests that zirconium is a good candidate material for the distillation portions of formic acid plants, in which the acid concentration and the temperatures are both high (Ref 10).

Nonmetals. Formic acid is an excellent solvent, which makes it very destructive to most organic materials and coatings. Therefore, plastics are not normally considered for this service. An exception is polyethylene, which is good with all concentrations to about 35 °C (95 °F). The fluorocarbon plastics are resistant to their normal temperature limitations, except as coatings, which have a temperature limitation of about 93 °C (200 °F).

Hard rubber, neoprene, and butyl rubbers are resistant at ambient temperatures and fluor-elastomers to about 50 °C (120 °F). Rubber linings can be used for storage if discoloration of the acid is not a matter of concern.

Acetic Acid

Acetic acid is made by a variety of processes, the best known being the butane oxidation and the Monsanto low-pressure processes. Historically, acetic acid was produced by fermentation of grain and then by oxidation of acetaldehyde. The fermentation process was usually carried out in copper equipment or wooden tanks, and combinations of copper and stainless steel equipment were used for acetaldehyde oxidation.

The Monsanto process is based on the carbonylation of methanol (with carbon monoxide) using a rhodium catalyst and an alkyl halide such as methyl iodide. This process has all but replaced the now-antiquated Wacker Process (Ref 9). The Monsanto process (and various improvements thereof) is the most popular method for the production of acetic acid. As can be surmised, the addition of the halogen reaction promoter to the reaction cycle requires the use

of very corrosion-resistant alloys and spreads trace halides throughout the rest of the plant. Various patents have been filed to overcome the corrosion caused by the halogens that are in the reaction cycle. These have varied from the use of silver compounds to form insoluble silver salts to distillation schemes to minimize carrying bromides into other parts of the plant. The bromide addition, if carried downstream in sufficient quantities, certainly has the potential to pit, crack, and corrode the stainless steel used in the downstream equipment. Data derived directly from the field exposure of alloys are not available, but the problems facing the corrosion engineer who selects materials for these processes have been outlined in Ref 11. The reaction system contains the halogen promoter, and it has been suggested that alloy B should be tested along with titanium, zirconium, and tantalum for this high-pressure, high-temperature system (Ref 11). Nickel-molybdenum and nickel-copper alloys are considered attractive for the recovery system that still contains the halide, using the more conventional materials only to handle the acid after the halide has been removed (Ref 11). Excellent corrosion resistance of commercially pure zirconium in the reaction system has been reported in Ref 12.

Steel is attacked quite rapidly, with hydrogen evolution, at concentrations stronger than 1×10^{-3} molar, even at room temperature. Glacial acetic at room temperature is less aggressive than aqueous solutions of the acid, but still causes a corrosion rate of attack of 0.8 to 1.3 mm/yr (30 to 50 mils/yr). Therefore, steel is normally unacceptable for use in acetic acid service.

Aluminum shows good resistance to nearly all concentrations of acetic acid at temperatures up to 50 °C (120 °F). Alloys 1100 (A91100), 3003 (A93003), and those from the 5000 series such as 5052 (A95052) are used for storage and shipment of the acid. It is rapidly attacked below about 95% acetic acid at the boiling point and is again attacked very rapidly in concentrations near 100% or in those mixtures containing excess acetic anhydride. Aluminum again becomes resistant to pure acetic anhydride, although it causes contamination of the anhydride due to formation of a white crystalline solid, aluminum triacetate, which precipitates in the liquid. The copper-bearing 2000-series, alloys of aluminum are not suitable for acetic acid service because of high corrosion caused by the copper-rich precipitates.

An excellent summary of the use of aluminum in acetic acid and anhydride has been published in Ref 13. Figures 6 and 7 show the resistance of aluminum in acetic acid and acetic anhydride, $(\text{CH}_3\text{CO})_2\text{O}$. The data are for aluminum 1100, but similar rates would be expected for alloys such as 3003, 6063 (A96063), or 5086. The corrosion resistance of aluminum is strongly affected by contaminants in acetic acid, and aluminum can corrode in almost any concentration of acetic acid at any temperature

if the acid is contaminated with the proper species.

Copper and Copper Alloys. With the exception of the alloys that contain more than 15% Zn, copper (C12000) and all of its alloys show good resistance to all concentrations of acetic acid up to and even above the atmospheric boiling temperature in the absence of oxygen or other oxidants. This good performance is predicted by the previous discussion on corrosion characteristics of the electrochemical stability of copper in organic acids. Copper was used almost exclusively to handle acetic acid until the advent of stainless steels; today type 316L stainless steel and higher alloys are often used. Type 316L stainless is not always the best solution. A case was reported in which type 316L was badly attacked in air-free hot acetic acid service, whereas copper under the same conditions was acceptable (Ref 14). The absence of oxidizing agents is a requirement for copper to be usable in acetic acid solutions, as well as other organic acids. Slight contamination of acetic acid with air, through storage under an air atmosphere or by ingress of air through a vacuum leak, can increase the corrosion to rates that are unsuitable. Copper is nearly immune to attack by pure, uncontaminated acetic acid.

Laboratory tests that introduced oxygen into room-temperature 50% acetic acid gave corrosion rates of 1.9 mm/yr (76 mils/yr) compared to only 0.08 mm/yr (3.2 mils/yr) in nitrogen blanketed tests. Similar data in 6% acetic acid showed a corrosion rate of only 0.03 mm/yr (1.2 mils/yr) when passing hydrogen over the solution, whereas when oxygen is passed over the solution, the rate rose to 0.58 mm/yr (23 mils/yr) (Ref 1). Copper alloyed with increasing quantities of nickel showed increased corrosion resistance to acetic acid. The nickel addition also increased the resistance to the effect of oxidants. Tests in air sparged with 50% aqueous acetic acid at the boiling point gave rates of 7.75 mm/yr (310 mils/yr) for copper, 4.7 mm/yr (188 mils/yr) for copper containing 30% Ni, and 2.1 mm/yr (84 mils/yr) for copper containing 70% Ni. Similar reductions in corrosion rates with increasing nickel

Fig. 6 Effect of concentration and temperature on corrosion of 1100-H14 (A91100) aluminum alloy in acetic acid

content were noted when ferric ion was added to the solution. However, the rates still are too high for economical use even though the nickel addition was beneficial—again pointing out the harmful effects of oxidizing impurities. A 10% aluminum bronze alloy (C61800) is reported to be a superior copper alloy for handling acetic acid with rates of 0.05 to 0.07 mm/yr (2 to 3 mils/yr) in boiling glacial acid (Ref 15).

Stainless Steels. Low corrosion rates for the straight chromium 400-series stainless steels in dilute acetic acid solutions can often be shown in laboratory tests. However, these alloys exhibit very tenuous passivity, and field experience with these materials indicates a susceptibility to high corrosion rates and pitting attack. An exception is a high-purity chromium-molybdenum ferritic stainless steel such as alloy 26-1 (S44627) that shows good resistance.

Type 304L (S30403) stainless steel is the lowest grade commonly used. Type 304 (S30400) stainless steel finds wide use in dilute acetic acid solutions and in the shipment and storage of concentrated acetic acid. Previously published data (Ref 4) show that glacial acetic acid can be handled in type 304 to a temperature of about 80 °C (175 °F), and it has been satisfactory for lower concentrations to the boiling point of the acid. Intergranular corrosion of sensitized type 304 stainless steel will occur in 60 °C (140 °F) and hotter acetic acid. To prevent this intergranular attack, the use of the low-carbon grade 304L is recommended for welded construction. The effect of oxidizing impurities cannot be overlooked when using type 304 stainless steel. The hotter the solution, the more critical is the presence of adequate quantities of oxygen or other oxidizing impurities. If oxidizing conditions are lost, rapid corrosion can ensue.

Type 316L stainless steel is the alloy most commonly used in equipment processing acetic

Fig. 7 Metal loss for 1100-H14 (A91100) aluminum alloy in acetic-acid/acetic-anhydride solutions at atmospheric boiling temperature

acid. Even glacial acid at temperatures above the atmospheric boiling point can be handled if the impurities are held within proper levels. The low-carbon grade 316L is required for the higher-temperature applications where welding is required. Type 316L, rather than type 304L, is most often the required alloy for tankers shipping commercially pure acetic acid because of the lower metal pickup from corrosion.

The old acetaldehyde oxidation process for manufacturing acetic acid also produced acetic anhydride as a coproduct, and it is often found in acetic acid streams. If acetic acid contains only small quantities of acetic anhydride or if the acid is truly anhydrous, the rate of attack on type 316L is very high. The introduction of just a few tenths percent of water will reduce the corrosion back to normal rates. Figure 8 illustrates the reduction in corrosion rate as more acetic anhydride is added.

Leakage of chloride-bearing water to acetic acid process streams (e.g., from leaking condensers) results in contamination of the acid with sodium chloride, with subsequent formation of hydrochloric acid. The hydrochloric acid can then move through the system causing its own problems. Corrosion of stainless steel equipment by the hydrochloric acid, for example, produces ferric chloride (along with chromium and nickel chlorides) which, because of its volatility and strong oxidizing nature, is particularly pernicious. The volatility of ferric chloride allows it to move freely through a processing system, and, because it is a strong oxidant, it promotes stress-corrosion cracking (SCC). Besides SCC, a condition of accelerated corrosion and pitting results from chloride contamination. Reportedly, slightly less than 20 ppm of chloride in the organic acid stream can be tolerated, but higher concentrations are likely to cause rapid equipment failure (Ref 16).

Heat transfer, as in heat exchangers, can alter the corrosion mechanism and corrosion rate.

Fig. 8 Laboratory corrosion rates of type 316 stainless steel (S31600) in acetic acid/acetic-anhydride mixtures

A method to test metals under heat-transfer conditions has been described in Ref 17, and data on stainless steels and some nickel alloys under heat transfer conditions have been developed. Higher alloys such as alloys 20 (N08020), 825 (N08825), 904L (N08904), and the 6% Mo superaustenitic stainless steels show better resistance to acetic acid than does type 316 stainless steel—especially when being used to heat the acid, for example, in evaporators. Alloy 20 weld overlay has been used successfully to combat crevice corrosion of type 316 stainless steel in areas such as flange faces.

The duplex stainless steels that contain molybdenum are very good in boiling acetic acid. Among the duplex grades, alloy 2205 offers an advantage over type 316L in the presence of chlorides. In 80% acid containing 2000 ppm chlorides at 90 °C (195 °F), it showed a rate of less than 0.05 mm/yr (2 mils/yr) versus greater than 1 mm/yr (40 mils/yr) for type 316L. However, in boiling 99.5% acid with 200 ppm chlorides, alloy 2205 exceeded 1 mm/yr (40 mils/yr), whereas alloy 2507 corroded at less than 0.02 mm/yr (0.8 mil/yr) (Ref 6).

Titanium is resistant to all concentrations of acetic acid up to the atmospheric boiling point. Electrochemical corrosion studies in acetic acid solutions suggest that it is possible to attack titanium in anhydrous acetic acid, although titanium has been successfully used in commercial practice. However, some failures of titanium in hot strong acetic acid have been reported with most failures associated with hydrogen embrittlement. Laboratory tests confirmed hydrogen absorption in 95% acid at 210 °C (410 °F) with 1000 ppm hydrobromic acid. Titanium is often used for the reactors in the production of terephthalic acid by the air oxidation of xylene using cobalt, manganese, and hydrogen bromide (HBr) catalysts. In these processes, acetic acid is used as the reaction solvent. Even when chlorinated feedstocks such as mono- and dichloro-terephthalic acid are used, titanium can be made to work if the HCl that is generated by decomposition is prevented from condensing on unwashed surfaces. The high-strength titanium alloys should not be used because of their propensity for SCC.

Zirconium is resistant to all of the concentrations of acetic acid that titanium is resistant to but does not appear to be subject to corrosion in anhydrous conditions or to corrosion from condensation on unwashed surfaces. It is used in the iodide-catalyzed methanol/carbon-monoxide production process for acetic acid. For reasons not fully understood, zirconium is not good if copper ions, especially cupric chloride, are present in hot strong acetic acid/anhydride mixtures (Ref 12).

Nickel Alloys. Alloys C-276 and B-2 are resistant to acetic acid solutions at all normal concentrations and temperatures. These materials are sometimes used where the acetic acid is mixed with inorganic acids and salts, which limits the use of stainless steel or copper alloys. Alloy B-2 is used under reducing conditions,

such as with combinations of acetic acid and sulfuric acid, while alloy C-276 is commonly used in acetic acid solutions, which are highly oxidizing in nature. Alloy C-276 has been used for glacial acetic acid evaporators.

Other Alloys. Silver has been used frequently in European practice to handle acetic acid, and it is quite resistant to all concentrations at normal temperatures. Because silver has a higher electrochemical potential than copper, it is much more resistant to acids contaminated with metals ions such as iron and copper. Because of cost considerations, silver has found very little continued use.

Nonmetallic Materials. In the food industry, wooden stave storage tanks have been used for the storage of dilute acetic acid, and many years of service are common with wood tanks in 3 to 4% acid. However, stainless steel tanks are now widely used with the exception of pickle production, wherein copious amounts of salt are dissolved in the weak acid.

Successful use of both hard and soft rubber linings has been experienced in the storage of acetic acid, provided that discolorization of the product is not objectionable. Soft rubbers tend to swell. Butyl rubber will withstand glacial acetic acid to about 80 °C (175 °F). Ethylene-propylene rubber is satisfactory above 5% concentration at room temperature.

Of the plastic materials, polyethylene drums are used to handle chemically pure glacial acetic acid. The fluorinated plastics are completely resistant to their normal temperature limits. Many plastics tend to be susceptible to solvent action by the acid. Of the thermosetting resins, chlorinated polyethers and furanes have been used to about 100 °C (212 °F). Reinforced phenolics are suitable to about 120 °C (250 °F). Glass-reinforced plastic construction using a bisphenol polyester and vinyl esters has been successfully employed.

Carbon and graphite are resistant to the boiling point, and impervious graphite heat exchangers have been used in many demanding acetic acid services.

Glass linings have been used to handle acetic acid. No attack on borosilicate glass is reported below about 149 to 177 °C (300 to 350 °F). When the glass is attacked, it becomes porous and fades from a dark blue to a pale blue via ion exchange. This is easily detected by simple wetting of the surface to detect a color change.

Propionic Acid

Propionic acid or methyl acetic acid boils at 141.4 °C (286.5 °F) and is water soluble. It is a weaker acid, but otherwise very similar to acetic acid.

Steel is attacked at rates of about 0.6 mm/yr (24 mils/yr) in pure propionic acid at room temperature and at much higher rates in aqueous solutions of the acid. Steel has very limited usefulness in propionic acid.

Aluminum will resist 100% propionic acid at room temperature, but becomes unacceptable at about 80 °C (175 °F). The corrosion diagram displayed in Fig. 9 shows that the attack is very similar to that in acetic acid (Ref 4). Like acetic acid, if the propionic acid is contaminated with anhydride or heavy metal ions, high rates are possible.

Copper and copper alloys containing not more than 15% Zn will handle propionic acid in all concentrations. The data shown in Fig. 10 indicate attack on copper in boiling 100% propionic acid, but this is believed to be an anomaly caused by incomplete deaeration of the solution since propionic acid been routinely handled in copper-lined equipment. As with formic and acetic acid, copper and its alloys are satisfactory only if the solutions are completely deaerated and do not contain other oxidizing agents (Ref 1).

Stainless Steels. The 400-series stainless steels will pit in propionic acid solutions, probably because of borderline passivity, and are therefore unreliable. They should not be used unless they are tested in the exact environment.

Type 304 stainless steel shows good resistance to propionic acid at room temperature and to aqueous solutions up to about 50% concentration at the atmospheric boiling point. Field experience has been that type 304 demonstrates borderline passivity above 80% and is not suitable for such service.

Figure 10 shows the resistance of various materials, including type 316 stainless, to boiling propionic acid solutions. These were short-term tests in which the gaseous atmosphere above the boiling solutions was not controlled. It is likely that this resulted in two erroneous results (Ref 1). The rate of copper corrosion was found to increase rapidly above 65% concentration but copper would have very low corrosion rates at all concentrations if the atmosphere above the solution was oxygen free. Secondly, type 304 stainless steel was shown to have decreasing corrosion rates between 80 and 100% concentration which is not borne out by field experience. Field experience shows that type

304 stainless steel exhibits border-line passivity in this range of concentrations at the boiling temperature and should not be considered for such service.

Type 316L stainless steel and the molybdenum-containing duplex stainless steels, such as alloy 2205, are the preferred material for handling hot concentrated solutions of propionic acid. The low-carbon grades should be utilized to avoid possible intergranular attack. They are quite suitable for all ranges of concentration, noting that oxidizing conditions are beneficial and that the rate can be somewhat high around 65% concentration as show in Fig. 10 (Ref 21).

Nickel Alloys. Alloys B-2 and C-276 show excellent resistance to propionic acid solutions under reducing and oxidizing conditions, respectively. Other nickel alloys of similar composition show similar good resistance to propionic acid, but are not normally used since type 316L is suitable for most concentrations at high temperatures and is much less expensive.

Other Organic Acids

The solubility in water decreases with increasing molecular weight of the aliphatic mono acids (e.g., butyric, pentanoic, etc.). Such acids are usually noncorrosive to type 304L, for example, until the temperature becomes high enough to promote dissociation. This critical temperature is usually close to the atmospheric boiling point, at which temperature type 316L is usually required.

It is impossible to cover here the corrosion characteristics of the many different organic acids. However, a sampling of corrosion rates of various metals in several of the longer chain aliphatic acids, aromatic acids, and some dicarboxylic acids is shown in Tables 3 and 4 (Ref 9). Table 4 shows data on the corrosion of some less familiar alloys in various organic acids.

Steel is usable at ambient temperatures in the higher molecular weight acids, and it is used conventionally to store many of the acids and their corresponding anhydrides.

Aluminum shows good resistance to the acids at room temperature and is widely used for their handling. Some of the higher molecular weight acids cause severe attack of aluminum at highly elevated temperatures; therefore, the use of aluminum must be considered for the specific acid and temperature desired.

Copper and copper alloys exhibit good resistance to all of the higher molecular weight acids and can be used quite widely to handle the acids, even at elevated temperatures in the absence of oxidants.

Stainless Steels. Type 304 stainless steel has excellent resistance to the higher molecular weight organic acids at room temperature and at lower concentrations at high temperatures. With the concentrated acids, type 304 is sometimes severely corroded. Type 316 stainless steel is then required and is usable in almost all of the acids, even at elevated temperatures.

Nickel Alloys. The Ni-Mo and Ni-Mo-Cr alloys show excellent resistance to the higher molecular weight acids, but the expense of these alloys is rarely justified unless other contaminants, such as inorganic acids, are also present. The nickel alloys, particularly nickel-copper, have been used to process the higher molecular weight acids at elevated temperatures. They can be particularly useful when contamination of the acids prohibits the use of type 316 stainless steel.

Corrosion by Hydrogen Chloride and Hydrochloric Acid

Revised by J.R. Crum, Special Metals Corporation

HYDROCHLORIC ACID (HCl) is an important mineral acid with many uses, including acid pickling of steel, acid treatment of oil wells, chemical cleaning, and chemical processing. It is made by absorbing hydrogen chloride in water. Most acid is the by-product of chlorinations. Pure acid is produced by burning chlorine and hydrogen. Hydrochloric acid is available in technical, recovered, food-processing, and reagent grades. Reagent grade is normally 37.1% (Ref 1). Hydrochloric acid is a corrosive, hazardous liquid that reacts with most metals to form explosive hydrogen gas and causes severe burns and irritation of the eyes and mucous membranes. Safe handling procedures for HCl are described in Ref 2. Additional safety information is available from the manufacturer.

Concentrated HCl is transported and stored in rubber-lined or fiberglass-reinforced plastic (FRP) tanks, although plastic-fabricated polyester-reinforced thermoset plastic storage tanks have also been used. Pipelines are usually plastic-polypropylene-lined (PP) steel or FRP. Processes involving aqueous acid are commonly carried out in glass-lined steel equipment. Nonmetallic materials are normally preferred, when possible, because of the corrosive action of this strongest of acids on most metals.

Candidate metals and alloys for handling HCl are shown in Fig. 1. Materials are judged to be suitable if they have a corrosion rate under 0.5 mm/yr (20 mils/yr) when exposed to uncontaminated HCl. Several metals or alloys have useful corrosion resistance in low concentrations of HCl. As the concentration and temperature increase, the corrosivity increases dramatically. As a result, the selection of metals and alloys becomes more limited, as shown in Fig. 1. In practice, contamination is not uncommon and can be catastrophic. Selection of a candidate metal should be based on extensive corrosion testing or, preferably, field experience, using the grade of acid that will be available.

Effect of Impurities

Hydrochloric acid may contain trace amounts of impurities that will change the aggressiveness of the solution.

Fluorides. Acid recovered from the manufacture of fluorocarbons may contain trace amounts of HF. It has been reported that such acids may contain more than 0.5% HF (Ref 4). Commercial suppliers remove most of the fluoride from HCl by selective absorption, and it is unlikely that an unsuspecting customer would receive acid containing as much as 0.5%. However, glass-lined steel and the refractory metals, such as zirconium, niobium, tantalum, and titanium (but not molybdenum), have very low tolerance levels for fluorides. Zirconium is reported to tolerate less than 10 ppm (Ref 5). Tantalum may tolerate 10 ppm or more. The limits are undefined except for a few specific cases, and it is best to consider all of these metals and glass-lined steel to be essentially non-resistant of fluorides and to know the source and specification limits of the acid if these materials are used.

Ferric Salts. The presence of Fe^{3+} ions in HCl has a profound effect on the corrosion of many metals and alloys otherwise resistant to HCl. Nickel-base alloys, including alloy B-2 (UNS N10665), the copper alloys, and unalloyed zirconium, are affected. Although the acid specification may be low in iron, acid can easily become contaminated during shipment and handling.

Cupric Salts. Cupric ions have an accelerating effect on the corrosion of many metals that is similar to that of Fe^{3+} ions. Like Fe^{3+} ions, Cu^{2+} ions can cause pitting and stress-corrosion cracking (SCC) of zirconium. The presence of Cu^{2+} ions can also lead to the autocatalytic acceleration of nickel-copper and copper-nickel alloys. It is unlikely that commercial acid would contain Cu^{2+} salts. This is more of a problem of in-process contamination by exposure of copper-containing metals or introduction as an impurity in a chemical or raw material used in the process.

Aeration, although less damaging than the presence of oxidizing metal salts, accelerates the corrosion of many metals. Figure 2 shows the effect of aeration on the corrosion rate of Nickel 200 (UNS N02200) and alloy 400 (UNS N04400).

Chlorine contamination accelerates the corrosion of all metals except unalloyed tantalum and noble metals; however, unalloyed titanium can be protected by the presence of chlorine in dilute HCl (Ref 6). Chlorine may be present in acid recovered from a chlorination process but would be removed before sale.

Organics. Hydrochloric acid can become contaminated with organic solvents, such as carbon tetrachloride (CCl_4) or chlorobenzene ($\text{C}_6\text{H}_5\text{Cl}$), when recovered as a by-product of a chlorination process. Even a few parts per million of organic contaminants can, over a period of time, destroy rubber linings, elastomer membranes behind brick linings, and certain plastics and elastomers. It is unlikely that such acid would be shipped, although organic contamination is often encountered in plant processes.

Corrosion of Metals in HCl

Most corrosion data and graphical information published by metal suppliers and others are based on tests conducted in reagent-grade HCl. In some cases, as in Fig. 1, limitations will be noted regarding the presence of aeration or impurities. As mentioned previously, these data should be used only as a guide in selecting metals for further testing and evaluation.

Carbon and alloy steels are unsuitable for exposure to HCl except during acid cleaning.

Austenitic Stainless Steels. The commonly used austenitic stainless steels, such as types 304 and 316, are nonresistant to HCl at any concentration and temperature. At ambient temperatures and above, corrosion rates are high. Nickel, molybdenum, and, to a lesser extent, copper impart some resistance to dilute acid,

but pitting, local attack, and SCC may result (Ref 7). Subambient temperatures will slow the corrosion rate but will invite SCC. Type 316 stainless steel has been known to crack in 5% HCl at 0 °C (32 °F) (Ref 8). At high corrosion rates (>0.25 mm/yr, or 10 mils/yr), SCC is unlikely to occur. However, the corrosion products, particularly FeCl_3 , will cause cracking. Chlorides can penetrate and destroy the passivity (oxide film) that is responsible for the corrosion resistance of stainless steels, and the corrosion engineer should resist every attempt to use stainless steels in environments containing chlorides.

Fig. 2 Corrosion of Nickel 200 and alloy 400 in HCl solutions at 30 °C (85 °F). Source: Ref 5

Superaustenitic stainless steels and higher-nickel alloys possess useful resistance to HCl at lower concentrations, as shown in Fig. 3. Stainless steel 316 shows very little resistance, as mentioned previously, while resistance increases in alloys containing higher nickel and molybdenum contents. Some other higher-nickel alloys, such as 20Cb-3 (UNS N08020) and 825 (UNS N08825), with their high nickel content (32 to 42%), 2 to 3% Mo, and 3 to 4% Cu, resist HCl at all concentrations below approximately 40 °C (100 °F).

The standard ferritic stainless steels, such as types 410 and 430, should not be considered, because their corrosion resistance to HCl is lower than that of carbon steel. An exception is 29-4-2 stainless steel, which reportedly resists up to 1.5% HCl to the boiling point and remains passive (Ref 10). However, it is not suitable at higher concentrations, and the alloy is susceptible to SCC, although its resistance is reported to be high.

Nickel and Nickel Alloys. Nickel 200 and alloy 400 have good resistance (<0.25 mm/yr, or 10 mils/yr) to dilute (<10%) HCl in the absence of air or oxidizing agents at ambient temperatures. Alloy 400 has been used at concentrations below 20% at ambient temperatures under air-free conditions and under 10% concentration aerated, but penetration rates generally exceed 0.25 mm/yr (10 mils/yr) and may approach 1 mm/yr (40 mils/yr).

Increasing the temperature affects the corrosion rate of Nickel 200 more than that of alloy

Fig. 1 Metals with reported corrosion rates <0.5 mm/yr (<20 mils/yr) in HCl. Source: Ref 3

400 in 5% HCl (Fig. 4). When HCl is formed by hydrolysis of chlorinated hydrocarbons, acid concentrations are often less than 0.5%. Under these conditions, Nickel 200 and alloy 400 have found application at temperatures below 200 °C (390 °F) (Ref 5).

Alloy 600 exhibits corrosion resistance that is inferior to that of Nickel 200 and alloy 400 but has little, if any, catalytic effect on hydrolysis.

Fig. 4 Effect of temperature on the corrosion of Nickel 200 and alloy 400 in 5% HCl. Source: Ref 5

Many nickel alloys containing chromium and molybdenum have useful resistance to HCl in all concentrations up to approximately, 65 °C (150 °F) and in very dilute acid up to the boiling point (Fig. 5). Corrosion resistance increases with molybdenum content. The most resistant of these alloys, such as alloy C-276 (UNS N10276), also contain tungsten. The materials shown in Fig. 5 are useful for handling hot concentrated HCl, while the other materials discussed previously can only be relied on to resist minor HCl contamination in other chemical processes. These nickel-base, chromium- and molybdenum-containing alloys are also very resistant to chloride SCC. Resistance to pitting and crevice corrosion in acid chloride solutions improves with increasing chromium and molybdenum contents.

The most corrosion resistant of the nickel-base alloys to HCl are the B alloys (Ni-28Mo). Alloy B-2 (a more stable version of the original alloy B, or UNS N10001) is one of the few metals with a corrosion rate under 0.5 mm/yr (20 mils/yr) in all concentrations and temperatures up to the atmospheric boiling point in nonaerated acid in the absence of oxidizing agents (Fig. 6). Solution heat treatment of alloy B-2 after welding is required for maximum corrosion resistance. Alloys B-3 (UNS N10675) and B-4 (UNS N10629) are variations of this alloy, containing small amounts of chromium, that are more metallur-

Fig. 5 Comparative behavior of nickel-base alloys in HCl. The isocorrosion lines indicate a corrosion rate of 0.51 mm/yr (20 mils/yr). Source: Ref 11

gically stable and, as a result, more weldable and resistant to intergranular attack and SCC. However, small amounts of oxidizers, such as ferric ion, can destroy passivity of alloy B-2 and lead to high corrosion rates (Fig. 7). The presence of approximately 21% Cr in other high-molybdenum alloys, such as alloys C-22 (UNS N06022, 59Ni-21Cr-13Mo-3W-4Fe), 686 (UNS N06686, 59Ni-21Cr-16Mo-3.8W), and 59 (UNS N06059, 59Ni-23Cr-15Mo), promotes passivation in the presence of ferric ion contamination and leads to improved corrosion resistance (Fig. 8).

Alloy C-276 is another nickel alloy that has seen wide use in HCl service. It has excellent corrosion resistance (<0.13 mm/yr, or 5 mils/yr) in all concentrations of HCl at room temperature and good resistance (<0.5 mm/yr, or 20 mils/yr) to all concentrations up to 50 °C (120 °F). At concentrations under 10%, its resistance often exceeds that of B-2. Oxygen and strong oxidizing agents accelerate corrosion, although markedly less than for alloy B-2.

Copper and copper alloys have limited utility in HCl service because they are so sensitive to velocity, aeration, and oxidizing impurities. However, copper is one of the few

Fig. 6 Isocorrosion diagram for alloy B-2 in HCl

Fig. 7 Isocorrosion diagram for alloy B-2 to HCl with 500 ppm ferric ions. Source: Ref 12

common metals above hydrogen in the electromotive force (emf) series, and under reducing conditions, it can have low corrosion rates. An example is the use of silicon-bronze (UNS C65500) agitators and hardware in the manufacture of ZnCl_2 by dissolving zinc in HCl (Ref 8), with the evolution of hydrogen.

Typical corrosion rates for silicon bronze in HCl under nonaerated nonoxidizing conditions are 0.08 to 0.1 mm/yr (3 to 4 mils/yr) in up to 20% acid and 0.5 mm/yr (20 mils/yr) in concentrated acid at 25 °C (75 °F). At 70 °C (160 °F), rates are approximately 1 mm/yr (40 mils/yr) in up to 20% acid and over 6.4 mm/yr (250 mils/yr) in concentrated (35 to 37%) acid.

Corrosion-Resistant Cast Iron. A high-silicon iron alloyed with small amounts of molybdenum, chromium, and copper has good resistance to all concentrations of HCl to temperatures as high as 95 °C (200 °F). It is one of the few metals commonly used for pumps and valves in handling commercial grades of acid (Ref 7). Fluoride impurities are damaging.

Zirconium. The corrosion resistance of zirconium to HCl exceeds that of most metals, except tantalum and such noble metals as gold and platinum. Aeration does not have an appreciable effect. Corrosion rates are less than 0.13 mm/yr (5 mils/yr) at all concentrations to the atmospheric boiling point and above (Ref 13). However, chlorine and relatively small amounts of Cu^{2+} and Fe^{3+} ions accelerate

corrosion and can cause pitting and embrittlement. Figure 9 shows an isocorrosion diagram of zirconium in HCl.

It is important to avoid galvanic effects when connecting zirconium to other metals immersed in an electrolyte, because zirconium, like all the reactive metals, is sensitive to hydrogen embrittlement when it is the cathode of an electrochemical cell. Applications of zirconium equipment in HCl include pumps, valves, piping, and heat exchangers (Ref 13).

Titanium and Titanium Alloys. Although titanium has limited resistance to HCl, it is, unlike other metals, passivated rather than corroded by the presence of dissolved oxygen, Fe^{3+} and Cu^{2+} ions, nitrates, chromates, chlorine, and other oxidizing impurities (Ref 6). In commercial applications involving hot, dilute acid, enough impurities are often present to provide a high degree of protection. For example, the corrosion rate of unalloyed titanium in boiling 4% HCl was lowered from 21.4 mm/yr (843 mils/yr) to 0.01 mm/yr (0.4 mils/yr) by the addition of 0.2% FeCl_3 (Ref 6).

An isocorrosion diagram for unalloyed titanium and two titanium alloys is shown in Fig. 10. No titanium alloy has resistance to concentrated grades of HCl.

Tantalum and its alloys are the most resistant to HCl. Tantalum resists concentrations below 25% up to 190 °C (375 °F) and concentrations to 37% at temperatures to 150 °C (300 °F) (Ref 14). It was found that tantalum

is embrittled by concentrations of 25% or higher at 190 °C (375 °F) (Ref 14). Corrosion rates at that temperature were less than 0.025 mm/yr (<1 mil/yr) at 25% concentration or less, 0.1 mm/yr (3.9 mils/yr) at 30%, and 0.29 mm/yr (11.6 mils/yr) at 37%. Embrittlement was most pronounced in 37% acid. It also was found that corrosion and embrittlement could be avoided by coupling tantalum with platinum. This discovery formed the basis for the later development of the titanium-palladium alloy. Tantalum, like zirconium and titanium, is embrittled by the absorption of atomic hydrogen. This occurs if the metal is corroded in a nonoxidizing chemical or if it becomes the cathode of an electrolytic cell. For example, it is possible to embrittle tantalum plugs in a glass-lined vessel, if the vessel is equipped with an agitator of a metal lower in the emf series.

A comparison of reactive metals is made in Fig. 11. Nickel-molybdenum alloy B-2 and high-silicon steel, at the bottom of the figure, form a baseline for comparison. At temperatures above the HCl boiling point, tantalum and zirconium and their alloys and, in some cases, niobium are among the few metals or alloys that are resistant to attack.

Fig. 9 Isocorrosion diagram for zirconium in HCl solutions. Source: Ref 13

Fig. 10 Isocorrosion diagram for titanium in naturally aerated HCl solutions. Source: Ref 5

Noble Metals. Silver forms a protective chloride film in HCl and is resistant as long as the film is not dissolved or disturbed. At ambient temperatures, in the absence of oxidizing agents, silver resists all concentrations, with a corrosion rate of less than 0.025 mm/yr (<1 mil/yr) at concentrations of 20% or lower. At the boiling point, corrosion rates vary from 0.025 mm/yr (1 mil/yr) at 5% to 0.5 mm/yr (20 mils/yr) at 20%. Increasing the temperatures, aeration, and velocities will increase corrosion rates (Ref 7).

Refined gold is extremely resistant to all concentrations of HCl to and above the atmospheric boiling point. Oxidizing agents such as FeCl_3 and HNO_3 cause attack (Ref 7).

Refined platinum is almost as resistant as gold. It is slightly attacked by 36% acid at 100 °C (212 °F), the point at which gold shows no appreciable attack (Ref 7).

Nonmetallic Materials

Elastomers used in HCl service include natural rubber, neoprene, and others.

Natural rubber is used to line steel tanks, tank cars, and piping for handling commercial, uncontaminated, concentrated HCl (Ref 1). Natural rubber forms a protective rubber hydrochloride surface that slows further penetration, and a life expectancy of 20 years at ambient

temperature is not uncommon. The lining must be properly compounded for the service, must be of sufficient thickness (a minimum of 6.4 mm, or 0.25 in.), and must be properly applied and inspected. Soft rubber linings are recommended to 40 to 45 °C (100 to 110 °F), depending on the manufacturer (Ref 16, 17). A three-ply construction (soft-hard-soft) is often used to take advantage of the impermeability of the harder rubber and the resistance to damage, thermal shock, and abrasion of the soft rubber. Three-ply construction is recommended to temperatures of 55 °C (130 °F) (Ref 16). For higher temperatures, semihard rubber is recommended to 70 °C (160 °F), and hard rubber or flexible ebonite to a maximum temperature of 95 °C (200 °F) (Ref 18). The latter must be protected against exposure to sunlight and thermal and mechanical shock.

Natural rubber is severely affected by many organic contaminants, some of which may be present in by-product acid. Because the effect is cumulative, even trace amounts will eventually cause failure.

Neoprene. Although relatively unaffected by ambient-temperature HCl, neoprene is not recommended for linings, because of its permeability to concentrated acid (Ref 16, 17).

Other Elastomers. A number of elastomers have resistance to HCl that is as good as or better than that of rubber, but they are seldom used as linings for this service because of

economics and difficulty of application. However, they should be considered for exposure to sunlight, organics, higher temperatures, or flexing (the hard rubber hydrochloride surface cracks when flexed). These include butyl rubber, nitrite butyl rubber, ethylene propylene diene monomer, and chlorosulfonated polyethylene elastomer (Ref 18, 19). Fluoroelastomers have good resistance to hot acid, but because of high cost, are limited to small parts, such as gaskets and O-rings.

Thermoplastics. A large number of thermoplastics are suitable for handling all concentrations of HCl. Some of the most commercially important are described as follows.

Polypropylene. Polypropylene-lined steel pipe has largely replaced rubber-lined pipe for commercial HCl service, primarily because of economics and ease of field fit-up. Lined pipe is recommended for all concentrations of HCl to temperatures of 110 °C (230 °F) (Ref 20). Polypropylene is also available in small-to-moderate sized tanks and various molded shapes.

Polyethylene is unaffected by ambient-temperature acid, but its lack of stiffness, high thermal coefficient of expansion, and rapid falloff of strength with increasing temperature limit its use to underground or continuously supported pipelines. High-density cross-linked polyethylene is stronger and stiffer and is available in tanks up to 3785 L (1000 gal).

Polyvinyl Chloride (PVC). Both plasticized and unplasticized PVC have good resistance to HCl at ambient temperature. Unplasticized PVC piping systems are practical for complex systems that can be properly supported.

Polyvinylidene chloride has been used for many years as a lining for HCl pipelines. It is recommended for all concentrations to 80 °C (175 °F) (Ref 20). It has better resistance than rubber or polypropylene to certain hydrocarbons that may be present in process streams.

Polyvinylidene Fluoride (PVDF). Pipe lined with PVDF is recommended for all concentrations of HCl to 135 °C (275 °F) (Ref 20). Polyvinylidene fluoride is also available in lined valves and pumps. It resists a wide variety of other chemicals and solvents that may be present in process streams or in recovered acid. Linings, frequently reinforced with graphite, glasscloth, or veil, have been applied with multiple thermally fused layers with varying degrees of success. Each case should be approached with caution.

Fluoroplastics. In addition to PVDF, a number of other fluorocarbon plastics resist all concentrations of HCl at temperatures as high as 260 °C (500 °F) (Ref 20). The fully fluorinated polytetrafluoroethylene (PTFE) and perfluoroalkoxy have the highest temperature resistance and are the most expensive. Fluorinated ethylene propylene is limited to approximately 200 °C (400 °F) but is more easily molded than PTFE. Ethylene-chlorotrifluoroethylene and ethylene-tetrafluoroethylene are limited to 150 °C (300 °F) but have superior

Fig. 11 Hydrochloric acid isocorrosion diagram of 0.13 mm/yr (5 mils/yr) comparing tantalum, zirconium, niobium, high-silicon steel, and alloy B-2. Source: Ref 15

abrasion and permeability resistance (Ref 21). Most fluoroplastics are available as lined pipe, valves, and pumps (Ref 21).

Other Thermoplastics. Other plastics, such as acrylonitrile-butadiene-styrene, polysulfone, polyphenylene sulfide, and polyphenylsulfone, are resistant to HCl. Nonresistant thermoplastics include such polyimides as nylon and methacrylates.

Reinforced thermoset plastics for HCl service include polyester, epoxy, phenolic, and furan resins.

Polyester Resins. There have been a number of failures of glass-reinforced polyester resin storage tanks in concentrated HCl service. A life expectancy of 5 to 10 years has been reported (Ref 22). However, there are custom-built glass-reinforced plastic storage tanks that have given satisfactory service in concentrated HCl for 10 to 20 years and longer (Ref 8).

Standard, filament-wound storage tanks are not suitable for concentrated acid. Vessels should be fabricated in accordance with the standards detailed in Ref 23. The inner resin-rich layer should be thicker than 0.8 mm ($1/32$ in.), with two layers of veil (Ref 8). Bubbles and porosity are not acceptable, because they will cause blistering, which will lead to degradation. The novalac epoxy vinyl-ester resins resist blistering better than other resins, although none are recommended for storage of concentrated acid (Ref 22).

In Europe, glass-reinforced plastic tanks for storing concentrated acid are frequently lined with PVC sheet. The novalac resins have superior resistance to some chlorinated hydrocarbons (Ref 29). Custom-built storage tanks using this resin have been in service for over 10 years in concentrated acid containing CCl_4 in excess of solubility (Ref 8). Pumps and piping systems of polyester glass-reinforced plastic are also used for moving concentrated acid.

The epoxy resins are generally less resistant to HCl than the resistant grades of polyesters. Manufacturers of glass-reinforced plastic pipe limit recommendations for their epoxy pipe to concentrations of 10 or 20% at ambient temperatures, while the polyester pipe is recommended for all concentrations at higher than ambient temperatures. Recommendations by a leading manufacturer are given in Table 1. It should be

noted, however, that a noted pump manufacturer makes a silica-filled epoxy pump that is widely used for pumping concentrated HCl.

Phenolic Resins. Vessels, ducts, and piping systems fabricated of suitably filled phenolic resins will resist all concentrations of acid to temperatures as high as 175 to 200 °C (350 to 390 °F) (Ref 26). The phenolics are also resistant to many solvents. Because phenolic resins are weak in tension, equipment and pipe are often armored with epoxy-impregnated glass cloth or are filament wound. Piping systems must be carefully designed and installed with adequate support to minimize tensile stresses. Phenolic resins are often used as cements for brick linings.

Furan resins are also used to construct vessel duct and piping systems that are resistant to all concentrations of wet HCl (Ref 26). The solvent and alkali resistance of furan resins exceeds that of phenolics, and they are easier to handle during fabrication. Thus, furan glass-reinforced plastic vessels are available, and furan-glass membranes are used in brick-lined equipment. Temperature resistance is somewhat lower than that of the phenolics. Furans are the most common of the plastic cements used for brick linings.

Other nonmetallic materials for HCl service include impervious graphite, carbon, glass, glass-lined steel, and wood.

Impervious graphite is the most commonly used material of construction for HCl absorption and refining equipment. Resin-impregnated graphite equipment resists all concentrations of HCl to temperatures of 165 to 185 °C (330 to 365 °F), depending on impregnating resin and manufacturer. Polytetrafluoroethylene-impregnated graphite is reported to be resistant to a maximum temperature of 230 °C (450 °F) (Ref 27). By using graphite impregnated with

pure carbon, it is possible to increase the maximum-use temperature in air to 400 °C (750 °F) (Ref 27). Graphite has excellent thermal conductivity and chemical resistance (except to strong oxidants and concentrated H_2SO_4). However, it is extremely weak in tension and is seldom used for piping. Heat exchangers are available in block and crossbore construction to obtain more rugged units than shell and tube designs.

Carbon has poor heat transfer but excellent abrasion resistance. It is available as bricks for brick-lined construction. Like graphite, carbon resists all concentrations of HCl to 400 °C (750 °F) in air.

Glass. Complete small chemical plants are available in glassware. Piping systems can be obtained armored with glass fabric. Piping systems must be properly supported, because tensile stresses can result in delayed fracture.

Glass-Lined Steel. The corrosion resistance of a proprietary glass lining in HCl is shown in Fig. 12. The minimum thickness of high-voltage-tested glass linings is approximately 1 mm (40 mils). The calculated life expectancy may occasionally be somewhat greater than actual experience because of localized chains of bubbles. However, these data provide a reasonably realistic design basis.

Wood is an economical material for handling dilute acids. Tanks and large-diameter piping cost appreciably less than rubber-lined steel or thermosetting plastic construction. Although unsuitable for concentrated HCl, wood has excellent resistance up to 10% concentration. The National Wood Tank Institute recommends wood in 2% HCl to temperatures of 60 °C (140 °F) and 10% HCl to 70 °C (160 °F) (Ref 29). Cypress and fir were unaffected after 31 days of exposure in both 5 and 10% acid at room temperature and showed slight fiber disintegration and slight embrittlement and softening after 8 h in boiling 10% HCl (Ref 30).

For storage and handling of HCl, the following materials are usually considered adequate (Ref 31):

Application	Material
Tanks	FRP or rubber-lined steel
Tank trucks	Rubber-lined steel
Railroad cars	Rubber-lined steel
Piping	FRP or plastic-lined steel (e.g., PP)
Valves	PTFE or fluorinated ethylene propylene (FEP)-lined, cast alloy B (UNS N10001), N-12M(a)
Pumps	PTFE-lined, impervious graphite, cast alloy B(a)
Gaskets	Rubber, felted PTFE, FEP envelope, flexible graphite

temperature limits for various metals in HCl gas are shown in Table 3. These guidelines were developed from short-term tests. Because corrosion rates generally decrease with time as films and scales form, these limits have proved to be conservative. Temperature-versus-design corrosion rates for steel and several alloys are shown in Fig. 13.

The addition of water vapor to HCl gas has little effect on upper temperature limits. The addition of 0.2% water vapor by weight has been found to have no effect (Ref 33). However, water vapor has a severe effect at lower temperatures.

In a study (Ref 35), the suggested lower limit for carbon steel in a 60% H₂O, 40% HCl environment was 200 °C (390 °F) or slightly lower. The lower temperature limits for nickel alloys were 115 °C (240 °F) for C-276, 140 °C (285 °F) for alloy 625, and 260 °C (500 °F) for Nickel 200, alloy B-2, and alloy 600. Grade 7 (0.2% Pd) titanium had satisfactory resistance

**Fig. 13** Maximum temperature limits for various alloys in HCl service. Source: Ref 34

up to 120 °C (250 °F). None of the materials tested, including Nickel 200, titanium, zirconium, and cobalt-base alloys, was suitable at or slightly below the dewpoint. Minimum temperatures for metals ranged from 30 to 100 °C (85 to 210 °F) above the dewpoint, depending on the hygroscopicity of the corrosion products.

Corrosion by Hydrogen Fluoride and Hydrofluoric Acid

Herbert S. Jennings, DuPont Fluoroproducts

COMMERCIAL AQUEOUS HYDROFLUORIC ACID (HF) concentrations are provided in bulk at 49 and 70% by weight. By definition, anhydrous hydrogen fluoride (AHF) has less than 400 ppm water by weight. Both HF and AHF are of great industrial importance. Hydrofluoric acid is used for many industrial applications, such as etching and cleaning of metals and ceramics, acid treating oil and gas wells, and metallurgical ore and refining processes. Anhydrous hydrogen fluoride is consumed in the manufacture of fluorine and the production of fluorochemicals that are used to produce lubricants, plastics, and elastomers. Anhydrous hydrogen fluoride is also a catalyst for petroleum and chemical reactions.

The Hydrogen Fluoride Industry Practices Institute has guidelines for materials of construction for handling HF (Ref 1) and AHF (Ref 2). NACE International T5A171 (Ref 3) and Materials Technology Institute publication MS-4 (Ref 4) provide materials and corrosion data for critical design situations. More information can be obtained from HF and AHF producers, materials suppliers, and equipment fabricators.

Much of the data presented are from tests under ideal conditions with no impurities. Even in ideal conditions, corrosion rates may vary significantly from test to test. Test duration is important, because most metals form protective scales, and initial high corrosion rates will decrease with time to the rates found in commercial use (Ref 5). Corrosion rates of metals in HF and AHF are a function of concentration, velocity, temperature, impurities, and the nature of the corrosion product film. Corrosion reduces metal thickness and generates metal fluorides and atomic hydrogen.

The first part of this article presents corrosion data for materials in HF. The second presents data for AHF and includes discussions of hydrogen blistering and cracking of carbon steels and data for materials in high-temperature HF and AHF.

Aqueous Hydrofluoric Acid

Information on suitable materials of construction for handling HF of various strengths and at various temperatures is given in Ref 3 and

in alloy producers' literature. Figure 1 (Ref 3), an isocorrosion diagram for various metals, indicates temperature and concentration conditions where metals have corrosion rates of 0.5 mm/yr (20 mils/yr) or less. This figure is generated mostly from laboratory tests. Additional corrosion data for various metals in selected HF concentrations are shown in Tables 1 and 2 (Ref 6).

Carbon and Low-Alloy Steels

Carbon steels have useful corrosion resistance from 70 to 100% HF. In liquid concentrations below 70% HF, steel has a significant corrosion rate. Corrosion rates are reduced when HF solution temperatures are less than 20 °C (70 °F). Carbon steel in continuous exposure to 70% HF must be limited at temperatures no greater than 30 °C (90 °F). Under the influence of velocity, turbulence, or impingement, carbon steel is susceptible to erosion-corrosion; therefore, in 70% HF, it is a good practice to limit velocity to 0.6 m/s (2 ft/s). Increasing temperature, velocity, and aeration or lowering concentration can increase the corrosion rates of steels in HF.

Hydrofluoric acid vapors will condense at 38% concentration on surfaces that are at the dewpoint of 111.4 °C (232 °F). The concentration of condensing HF depends on the concentration of liquid HF. When the liquid is lower than 38% concentration and the temperature is below the dewpoint, the condensing vapor will be water enriched. However, above a liquid phase with higher than 38% HF concentration, the vapor phase condensate will be HF enriched. The HF-water/liquid-vapor equilibrium exhibits a constant boiling mixture or azeotrope at approximately 38 wt% HF. At 100 kPa (1 atm) or less pressure, there will be no condensation on surfaces that are above 111.4 °C (232 °F). Carbon steel corrosion data in HF liquid and vapor at 38 °C (100 °F) (Ref 7) are presented in Fig. 2. The maximum corrosion rate in liquid is at approximately 35% HF, 20 mm/yr (800 mils/yr). This high rate is indicative of the poor adherence and high solubility for ferrous fluoride

(FeF₂) and ferric fluoride (FeF₃) in 35 to 38 wt% HF. Steel in HF vapor exhibits a maximum corrosion rate at approximately 20% HF, 2.6 mm/yr (105 mils/yr).

Impurities in HF. Generally, carbon steel has higher corrosion rates in HF with air than without air. Notably, steel corrosion rates may be lowered by increased total acidity in HF by fluorosilicic and sulfuric acids. These impurities have a protective effect for steels in HF (Ref 8). Commercial HF quality has improved over time, so now these impurities are present in HF at only very low levels, and recent corrosion rates on steels tend to be higher than that reported in the 1950s.

Residual Elements in Carbon Steels. Parallel with changes in HF quality are changes in global steel-making practices, where more recycled metals are used. Some carbon steel products have slightly more residual elements (RE), such as copper, nickel, or chromium, than previous decades. These slight changes are a cause for higher steel corrosion rates in HF. Also, certain alloy steels exhibit high corrosion rates in HF. Dilute acids corrode iron and carbon steel at similar rates; compare the rates of iron and steel to those of alloy steels in Table 3. The HF causes exceptionally high corrosion rates on alloy steels with 1.35 to 17% Cr (ASTM A335 grades and type 430 stainless steels) (Ref 9).

Several HF alkylation units have reported corrosion of selective carbon steel piping or fittings that have slightly higher RE. These failures were associated with steels with slightly higher levels of copper, nickel, or chromium. The RE for all of the components was within nominal specifications for the pipe and fittings (Ref 10–14). The high-RE-component corrosion product layer was loose, porous, and nonprotective. Corrosion test data on low- and high-RE steels supported the relationship with corrosion performance (Ref 10). A 0.2% limit on RE for the sum of copper, nickel, and chromium (Σ_{RE}) was proposed for carbon steels in HF alkylation services. Electrochemical corrosion studies on high- Σ_{RE} samples indicated a diffusion-controlled anodic process (Ref 15). Low-carbon steel had lower corrosion rates than higher-alloyed steels in concentrated HF. Some RE were

beneficial or detrimental to corrosion resistance, depending on HF concentration and the presence of oxygen. The quantity and form of carbon in steel influenced corrosion in HF.

Another electrochemical study proposed reducing the 0.2% Σ_{RE} guideline to 0.15% Σ_{RE} (Ref 16). This study was performed with 60% HF at 71 °C (160 °F) and 1% HF at 40 °C (105 °F). An observation was that >0.18% C was beneficial for both low- and high- Σ_{RE} steel resistance. Copper and nickel were detrimental to corrosion resistance in HF. Chromium was beneficial for steels with >0.18% C but detrimental when carbon was lower. Tests in 1% HF found that this environment enabled galvanic corrosion. The low- Σ_{RE} steels were preferentially corroded, while high- Σ_{RE} steels exhibited lower corrosion

rates. Figure 3, from this study, presents normalized corrosion data from 60% HF at 71 °C (160 °F); the corrosion rates were lowest when carbon > 0.18% and $\Sigma_{RE} = 0.1\%$.

Galvanic corrosion is reported in 70% HF at 52 °C (125 °F) for carbon steels welded to higher alloys (Ref 17). Compared to 70% HF, the galvanic corrosion rates dropped significantly in 82 and 100% HF.

Austenitic Stainless Steels

Austenitic stainless steels have resistance to dilute HF. Type 304 stainless steel (UNS S30400) has very poor resistance to greater than 1% HF concentration. In concentrations over 5%

HF, type 304 exhibits higher corrosion rates than carbon steels at similar concentrations and temperatures. Type 316 stainless steel (UNS S31600) has useful resistance only at 23 °C (73 °F) or lower temperatures, at 10% HF concentrations or less, and this alloy may pit or crack under these conditions (Ref 18). Corrosion rates of type 316 are reported in Table 4 at 24 °C (75 °F) for 1 and 10% HF (Ref 19). Table 5 presents corrosion rates for type 316 exposed to 5% HF at 52 and 79 °C (125 and 175 °F) (Ref 20). Table 6 presents corrosion data for types 304, 316, and 309Cb (UNS S30900) (Ref 8). Weld fusion line corrosion has been observed on type 304 in dilute HF (<1%) and attributed to preferential corrosion of ferrite in the weld heat-affected zones (HAZs). Ferritic and martensitic stainless steels are subject to high corrosion rates and cracking in HF.

Cracking. Chloride stress-corrosion cracking (SCC) of sensitized type 304 is greatly aggravated by the simultaneous presence of acid fluorides (from weld electrode coating) and chlorides. Sensitized type 304 had SCC susceptibility to NaF over the range of 50 to 80 °C (120 to 175 °F) to 40 to 400 ppm F⁻, but with both Cl⁻ and F⁻, the SCC threshold dropped to 10 to 100 ppm F⁻ (Ref 21).

Nickel-Rich Austenitic Stainless Steels

In HF service, nickel-rich (nickel > 30%) austenitic stainless steels with chromium, molybdenum, and copper, such as alloys G3 (N06985), G30 (N06030), CN-7M (N08007), 20 (N08020), and 825 (N08825), have better resistance than other austenitic stainless steels but only over a slightly greater range of concentration and temperature, as indicated in Fig. 1. These alloys have good resistance to all liquid concentrations of HF at ambient temperatures and up to 10% HF at 70 °C (160 °F) (Ref 8). Corrosion data for alloys 20 and 825 in 1 and 10% HF are presented in Table 4. Also, data for alloy 825 are presented in Tables 5 and 6. The isocorrosion diagram (Fig. 4) includes data on alloys 825 and G30.

Weld Corrosion. In HF, the welds in alloys 20, 825, and G30 are more susceptible to corrosion than wrought metal. Weld attack by HF-HNO₃ is reported for alloys 825 (Ref 23) and G30 welded with electrode ERNiCrMo-11 (Ref 24). Weld attack is due to alloy segregation and the detrimental effect of reactive metals

(tantalum, niobium, and titanium) alloyed in the base and weld metals.

Oxygen Influence. Alloys 20, 825, G3, and G30 have higher corrosion rates when oxygen is present in HF liquid (Ref 25). In aerated HF, the alloys with better corrosion resistance have higher chromium and molybdenum, with nickel adding some limited benefits. In N₂-purged HF, the more resistant alloys contain nickel, molybdenum, and copper (G3 and G30).

Cracking of alloys 20 and 825 is reported in 10% HF vapors at 76 °C (169 °F) (Ref 19). The cracked samples had either a thin layer of copper deposit or significant staining, suggesting vapor-phase condensation corrosion, with accumulation and concentration of CuF on the sample surface. The CuF is oxidized to CuF₂ in the presence of oxygen. This may not occur when the metal is submerged in liquid HF, due to limited exposure to oxygen or dilution of corrosion products that reduce CuF on the metal surface. These alloys may experience SCC if exposed to low levels of fluorides with chlorides (Ref 26).

Nickel and Nickel-Base Alloys

Nickel and nickel alloys are among the more corrosion-resistant materials for HF. Figure 1 shows that nickel alloys from groups B and D are useful across the range of HF concentrations. In general, the corrosion rates of nickel alloys increase with HF concentration (up to the azeotrope of HF) and temperature. Nickel alloys and welds containing niobium tend to have elevated corrosion rates in HF above 40 °C (105 °F). Hydrofluoric acid liquid or vapor with oxygen increases corrosion of these alloys. The presence of oxidizing salts in HF may be beneficial to nickel-chromium alloys and detrimental to nickel-copper and nickel-molybdenum alloys. Corrosion data for various nickel alloys are presented in Fig. 4 to 6 as well as Tables 1, 2, 4, 5,

and 7 to 11 permitting comparison among these alloys and welds over a range of conditions.

Concentration. A general trend is that increasing HF concentration increases corrosion of nickel alloys at least up to the azeotrope. In contrast, Table 2 data on nickel alloys 400 and C trend to lower rates as concentration increases from 50 to 65% HF. The trend to higher corrosion is noticeable in Tables 4, 6, 7, and 8 as concentration increases from 1 to 48% HF. Similarly, this trend is noticeable in Fig. 1 (among group A alloys), Fig. 4 (for 10 nickel alloys), and in Fig. 5 (for 5 Ni-Cr-Mo alloys in 1 to 40% HF). In Fig. 5, several alloys have acceptable corrosion resistance at 10 to 20% HF at 79 °C (175 °F); however, at 20% and higher concentrations, there is divergence in corrosion resistance. Corrosion data for wrought nickel alloys should be considered with the weld data in Tables 7 and 8.

Temperature. Increasing temperature generally increases corrosion of nickel alloys in HF liquid and vapor (Tables 4, 5, 7, and 9). Figure 4

indicates that in liquid HF, only alloy 400 (UNS N04400) has acceptable corrosion at higher temperatures, while other nickel alloys are limited to lower concentrations with increasing temperature. Figure 6 presents corrosion data on alloys 400 and C2000 (UNS N06200) in 20% HF liquid and vapor over a range of 38 to 93 °C (100 to 200 °F) (Ref 20). One of the conclusions from this study was that nickel alloys containing high chromium and exposed in HF vapors had decreased corrosion rates with time, but when immersed, the corrosion rates were not dependent on time. The corrosion rates for alloys 400 and C2000 increased with HF concentration and temperature. Table 9 presents data from this same study for alloys 400, C276 (UNS N10276),

C2000, 242 (UNS N10242) and B3 (UNS N10675) in liquid 20% HF and vapor (Ref 27). At this concentration, liquid- and vapor-exposed alloys 400, C276, C2000, and 242 showed lower corrosion rates at 93 °C (200 °F) than at 66 °C (150 °F). This may indicate that during the 240 h test period, the corrosion product layer became more protective, or the oxygen in the system was reduced.

Alloys Containing Niobium. Nickel alloys containing niobium are prone to higher corrosion rates in HF. Table 5 includes corrosion data on wrought nickel alloys 625 (UNS N06625), C276, C22 (UNS N06022), and C2000 in 5% HF. Notably, from among these alloys, 625 had the highest corrosion rate at 79 °C (175 °F). This alloy has nominal 3.7% Nb. In Fig. 4, it is noticeable that among the Ni-Cr-Mo alloys, alloy 625 has the lower useful temperature (<40 °C, or 105 °F) in HF.

Weld Corrosion. Selective weld corrosion is common in HF. There are two primary causes for

**Fig. 4** Isocorrosion diagrams for various nickel-base alloys and 316L stainless steel in hydrofluoric acid liquid. Source: Ref 22**Fig. 5** Corrosion rates for various nickel alloys in 1 to 40% hydrofluoric acid (HF) at 79 °C (175 °F) for 24 h. Rates increase with HF concentration up to 20% HF, then corrosion behavior diverges. The x-axis is nonlinear. Source: Ref 20

weld corrosion. The first cause is segregation of certain elements in the cooling weld puddle. This is typical among nickel alloy welds and is notable by comparing the corrosion rates of welds to the base metal in Tables 7 and 8. Each weld has higher corrosion rates in comparison to the like base metal in corresponding test conditions. Alloy C22 (UNS N06022) weld samples had acceptable rates in both immersion and vapor exposure in 24 and 48% HF at 24 °C (75 °F). Alloy C22 welds had unacceptably high rates in liquid and vapors at both concentrations at 50 and 76 °C (122 and 169 °F). Although high, the alloy C22 weld samples had lower rates than alloy 400 weld samples in vapor exposure. In immersion conditions, alloy 400 weld corrosion rates generally were lower than rates of welded alloy C22 in similar conditions.

The second cause of selective weld corrosion is the alloying of niobium or other refractory metals in weld or base metals. Niobium affects the HF corrosion resistance of cast nickel-copper alloys M35-1 (N024135) and M30C (N024130) (Ref 28). Table 10 is HF corrosion data for these cast alloys and weld materials with various amounts of niobium. The cast alloy M35-1, with less than 0.5% Nb, had lower corrosion rates than M30C (1.3% Nb) in 49% HF. Weld deposits with

2.08% Nb had higher corrosion in aerated and nitrogen-purged 40% HF than those without niobium.

Hydrofluoric Acid with Oxygen: Liquid and Vapor Corrosion. Alloy 400 is used extensively in HF alkylation units and in the handling of HF. It has excellent resistance to liquid HF over the entire concentration range in the absence of oxygen to at least 150 °C (300 °F) (Ref 29). Alloy 400 has high corrosion rates in aerated 30 to 75% HF and even higher rates in HF vapor with air. Furthermore, denickelification of alloy 400 has been reported in aerated HF (Ref 5). Figure 6 shows that corrosion rates for alloy 400 in HF vapors can be higher than in liquid, and in these conditions, Ni-Cr-Mo alloys such as C2000 have better resistance. Oxygen increases the corrosiveness of HF for most nickel alloys but particularly for nickel-copper and nickel-molybdenum alloys. Data on a number of nickel alloys in HF liquid and vapor are presented in Tables 4 and 7. In Table 4, each wrought nickel alloy has acceptable corrosion rates when immersed in 1 and 10% HF during 72 h tests. However, alloys 200, 400, and 600 had higher corrosion rates in HF vapor (in air) than immersed samples and higher than (Ni-Cr-Mo) alloys C22 and C276. Table 7 presents data

on wrought alloys C22 and 400 exposed to 24 and 48% HF in 72 h tests. Immersion samples had lower corrosion rates than respective vapor

Fig. 6 Corrosion rates for alloys 400 and C2000 in 20% hydrofluoric acid liquid and vapors, 38 to 93 °C (100 to 200 °F), 240 h, showing comparable liquid rates but diverging vapor rates. Source: Ref 20

samples. Alloy 400 (wrought) immersed samples had acceptable rates in all conditions but unacceptable rates in all vapor-exposed conditions. Alloy C22 (wrought) immersed samples had acceptable rates up to 50 °C (122 °F). Alloy C22 (wrought) vapor samples had unacceptable rates at higher temperatures, but each vapor sample had lower corrosion rates than alloy 400 in comparable exposures. Table 9 presents corrosion data on nickel alloys in 240 h exposures to 20% HF liquid and vapor. High corrosion rates are noticeable for vapor-exposed alloys 400 and B3 versus liquid exposures; however, (Ni-Cr-Mo) alloys C276, C2000, and 242 had equal or lower corrosion rates in vapor versus those in liquid HF.

Corrosion test data from condensing conditions at 50 and 70 °C (122 and 158 °F) with 5% HF, 15% H₂O, and 8% O₂ are presented in Table 11. Corrosion rates at 50 °C (122 °F) on nickel-copper and iron-base alloys 400 and 25-6Mo (UNS N08926) were unacceptably high, but rates for Ni-Cr and Ni-Cr-Mo alloys 600, 622 (UNS N06022), 686 (UNS N06686), 825, and alloy C276 were low to moderate. The chromium-bearing nickel alloys were more resistant in the oxygen-rich HF. Corrosion rates at 70 °C (158 °F) were negligible due to little condensation.

Cracking. Alloy 400 samples, after exposure to vapors over 5 and 48% HF, had SCC in the base and weld metal of welded samples (Ref 30). Welded and stress-relieved samples made by the shielded metal arc weld process had SCC.

Oxygen and stress level were factors affecting the severity of SCC. No SCC was found on submerged samples; wrought, solution-annealed vapor samples; or welded and stress-relieved samples made by the gas tungsten arc weld process. Data from another investigation of nickel alloy SCC in HF are presented in Table 12. Alloys 400 and 500 (UNS N05500) in vapors of 48% HF at 60 °C (140 °F) had intergranular and transgranular SCC. Alloy 500, in the hot rolled or aged condition, was susceptible to SCC. Annealed or cold rolled alloy 400 U-bends cracked. Welded alloy 400 cracked in the base and weld metal. There was no SCC in air-free 48% HF after 30 days. However, alloy 500 cracked after 15 days in aerated immersion tests in 48% HF.

Alloy 400 cracking mechanism was unknown until it was found that aqueous HF solutions with cupric fluoride (CuF₂) would cause rapid SCC (Ref 32). Investigations on nickel-copper and copper-nickel alloys with HF and CuF₂ at 23 °C (73 °F) led to Fig. 7 and 8. Figure 7 indicates that when stressed to 80% of the ultimate tensile strength, alloys with 65 to 80% Ni required the least time to crack. The most SCC-susceptible composition was an alloy with approximately 69% Ni. Alloy 400 contains 63 to 70% Ni. Alloys with 70% Cu were not susceptible to SCC. Both increasing CuF₂ concentration in HF and tensile stresses reduced time for SCC. Figure 8 indicates that the time to crack alloy 400 in HF with CuF₂ is reduced by increasing stress and temperature.

Usually, SCC is found in the vapor phase due to condensation of HF vapor. A thin liquid film forms that is gradually enriched with CuF (cuprous fluoride) corrosion product as well as oxygen from the atmosphere, and CuF is oxidized to CuF₂. The bulk liquid phase provides much greater dilution of corrosion products, and oxygen absorption is confined to the liquid-vapor interface, thus limiting CuF₂ in the bulk solution. Preventing SCC requires total immersion and purging vapor spaces with nitrogen. Thermal stress relief is beneficial but has not always been successful in preventing SCC. As shown in Fig. 8, with time, SCC can occur at relatively low stress levels. Oxygen may enter when systems are opened for maintenance, in feed materials, or formed as a reaction product. General practice in HF alkylation service is to stress relieve cold-worked or welded alloy 400 at 621 °C (1150 °F).

However, nickel alloy and HF manufacturers recommend stress relief at 705 °C (1300 °F) for 2 h to avoid SCC of alloy 400. This is a prudent practice in systems where HF-exposed metal is rarely exposed to oxygen. However, stress-relieved alloy 400 exposed to HF, SO₂, and air has failed by intergranular corrosion after several years of service.

Cold rolled alloys 200 and 600 experienced SCC when exposed in vapors of 48% HF at 60 °C (140 °F), as shown in Table 12. Alloy 200 had intergranular cracking, while alloy 600 had transgranular cracking on the tension side. There are reports of SCC of alloys 200, C276, and B2 in HF with CuF₂ (Ref 32) and when located downstream from copper-bearing alloys.

Copper Alloys

Corrosion data on wrought and welded 70-30 copper-nickel (UNS C71500) in 5 and 48% HF are presented in Table 13. Higher corrosion rates occurred for vapor-exposed samples. Heat

Source: Ref 30

treatment had only a slight effect on corrosion rates. Although intergranular corrosion was noted, there was no SCC of 70-30 copper-nickel. The liquid-vapor interface and vapor-exposed samples had heavy corrosion. Copper alloys resist HF at very low velocities in the absence of air, oxygen, and other oxidizing contaminants. Copper tubing has been used for short-term services at ambient temperature in 70% HF free of oxygen. Copper sheets have been applied inside distillation columns in areas that are subject to HF accumulation.

Denickelification of 90-10 and 70-30 copper-nickel wrought and weld metals in a HF-H₂SO₄ mixture of 5 to 15% acid in water at 150 to 170 °C (300 to 340 °F) is reported (Ref 33). Severe denickelification was observed on 70-30 copper-nickel equipment, while 90-10 copper-nickel had only minor effects. Crevice areas had notable denickelification for both alloys. Welded 70-30 copper-nickel base metals had uniform corrosion, but welds had denickelification; corrosion data are presented in Table 14. The weld metal denickelification was two to eight times higher than the base metal. Denickelification was also reported on copper-nickel alloys in HF pressurized with air (Ref 5); however, denickelification was severe for alloy 400. Less nickel in the nickel-copper/copper-nickel alloy system reduces the susceptibility for denickelification in HF service.

Aluminum bronze and aluminum-silicon bronze dealloy and crack in HF exposure. Aluminum bronze (Ref 34) and aluminum-silicon bronze (Ref 35) are prone to dealuminification and intergranular SCC in HF. Copper-zinc alloys have not been used for HF services. Copper-zinc and some other copper alloys are subject to embrittlement or are sensitive to velocity.

Precious and Other Metals

Silver (UNS P07020), gold (UNS P00020), platinum (UNS P04995), tungsten (UNS R07005), and molybdenum (UNS R03600) are resistant to corrosion in HF of any concentration at ambient temperatures and, in most cases, to the

boiling point or higher (Ref 36, 37). Corrosion data for platinum and silver are presented in Tables 1 and 2. Also, iridium (UNS P06100), osmium, ruthenium, rhodium (UNS P05981), and palladium (UNS P03995) resist 40% HF at room temperature (Ref 38). Palladium may have higher corrosion rates in aerated HF or in HF with concentrated sulfuric acid.

Silver has low corrosion rates up to and above the HF boiling point and has been used in HF services such as stills, heating coils, condensers, rupture disks, and pressure diaphragms. However, silver in HF has high corrosion rates when also exposed to oxygen, hydrogen sulfide, or sulfur contamination (Ref 37). Sulfur compounds may be present in commercial HF.

Molybdenum has good resistance to HF. The corrosion rates of molybdenum in 25 to 50% HF at 100 °C (210 °F) are 0.4 to 0.5 mm/yr (16 to 20 mils/yr) in aerated acid. Rates in the absence of air are negligible (Ref 39). Molybdenum is used only for small parts that do not require welding.

Magnesium has good resistance up to 40% HF at 25 °C (77 °F), because the protective film formed is insoluble in aqueous acid. Corrosion data for magnesium are presented in Table 2. However, magnesium is infrequently used in HF service, because it has unacceptable corrosion in HF at higher concentrations and temperatures.

Reactive Metals. Hydrofluoric acid rapidly attacks reactive metals, niobium, tantalum, zirconium, and titanium, either as pure or alloyed metal. Even a percent or two of reactive metals in stainless or nickel alloys reduces their corrosion resistance to HF.

Nonmetals

Thermoplastics. Several thermoplastics are resistant to HF. Most have service limitations, but their lower costs and minimal contamination of HF make them candidates for consideration. Some thermoplastics change physical properties with exposure to HF. Also, when HF concentration is higher than the azeotrope, there will be AHF permeation through the plastic. Contamination, temperature conditions, mechanical damage, and ultraviolet light have caused thermoplastics to fail in service. Thermoplastics used in hazardous services such as HF are mainly applied as liners inside a metal or reinforced

Table 14 General and dealloying corrosion of welded 70-30 copper-nickel

thermosetting plastic vessel or pipe. Figure 9 presents maximum HF concentration and temperature for continuous use of plastics and elastomers in HF service (Ref 3), with the understanding that maintenance or replacement will be required after some time. Fully fluorinated thermoplastics are resistant to all HF concentrations up to and above the boiling point. Fully fluorinated plastics, such as polytetrafluoroethylene (PTFE), perfluoroalkoxy (PFA), and fluorinated ethylene propylene (FEP) do not lose strength, swell, crack, embrittle, and are not chemically attacked by HF. A chemically modified PTFE fluoropolymer, MFA (perfluoromethyl vinyl ether and tetrafluoroethylene copolymer), is weldable (Ref 40) and has increased permeation resistance (Ref 41) and improved deformation resistance under load and creep conditions. It is good practice to take care when installing fluoroplastic linings to avoid excess stress that can lead to internal liner damage and promote HF permeation. The

industry trend is toward fluoropolymer-lined equipment to minimize metal ion contamination of HF.

Other thermoplastic materials, such as polyethylene, polypropylene, chlorinated polyvinyl chloride (CPVC), and polyvinyl chloride (PVC), are less costly but are limited to lower temperatures and concentrations below 70% HF, as seen in Fig. 9. Tanks fabricated from high-density polyethylene (HDPE) ribbon as helical weld seams have provided over 15 years of satisfactory service in concentrations of 5 to 70% HF at ambient temperatures and atmospheric pressure, with no measurable deterioration of properties (Ref 42). Cross-linked polyethylene tanks have provided over 15 years of service in HF service at ambient temperatures. Small midwall blisters, containing HF, have formed in low-density polyethylene and HDPE after a year exposure to concentrations over 60% HF at 30 °C (85 °F) but with no deterioration of mechanical properties. However, a rotational-molded HDPE tank

cracked through the wall at the bottom knuckle by environmental stress cracking after two years of service (Ref 43). Unplasticized PVC and CPVC have resistance to HF solutions and AHF vapors; however, PVC and CPVC plasticized with vinyl acetate or vinyl chloride is not resistant.

Reinforced Thermosetting Plastics. Reinforced thermosetting plastic resins commonly recommended for HF services are epoxy vinyl esters (Ref 44). However, these have been limited to 10% HF concentrations below 65 °C (150 °F). The corrosion-resistant barrier typically has at least a double layer of apertured synthetic polyester, apertured ethylene chlorotrifluoroethylene, or carbon-reinforcing veil materials. Additional information may be obtained from manufacturers and fabricators.

Elastomers. Carbon-filled and peroxide-cured fluoroelastomers and perfluoroelastomers have been used as O-rings in all HF concentrations at ambient temperatures and above. Generally, elastomers with higher fluorine content have better HF resistance (Ref 45). Consult manufacturers for guidance on the best compounds, fillers, and cures for a specific HF service.

As seen in Fig. 9, several rubber types are useful in HF concentrations below 60% at temperatures below 70 °C (160 °F). Consultation with the rubber supplier is essential to assure that available rubbers will have low silica or magnesia compounding (below 0.3 wt%) for HF service. Some rubber suppliers may be unaware that clays they use as additives contain silica and magnesia compounds. Specially formulated chlorobutyl rubber is used for lining containers for 70% HF. In 70% HF, the useful life of chlorobutyl in warm climates is approximately three years, while in cool climates it is four to six years. Longer chlorobutyl service life is experienced with lower HF concentrations. Bromobutyl rubber is used in HF service in Europe. Table 15 presents 50% HF elastomeric exposure data at 22 °C (72 °F) (Ref 46).

Carbon and graphite are resistant to HF. Impervious graphite impregnated with PTFE fluoropolymer has provided satisfactory service to at least 80% HF at 150 °C (300 °F) but may be prone to AHF permeation. Impervious graphite impregnated with phenolics has provided satisfactory service to 110 °C (230 °F) for 48% HF and to 85 °C (185 °F) for 60% HF. Impervious graphite impregnated with furan has cracked in

HF services (Ref 47). Carbon brick linings (ash content <1%) with phenolic mortar and fluorinated plastic membranes have been applied in carbon steel vessels for high-temperature HF-water scrubbers. Flexible graphite has been used for gaskets and packing materials in HF services. Carbon-carbon composites have excellent resistance to HF (Ref 48); however, their use is limited to internal components, because they are permeable.

Alumina, Sapphire, and Carbides. Alumina (>99.7% purity) and sapphire have resistance to HF. Sintered silicon carbides (100% alpha grade) have been used for pump bearings in HF service. Sintered silicon carbide fibers had essentially no mass loss in 53% HF at 25 °C (77 °F) in 125 h (Ref 49).

Commercially available polycrystalline alumina and sapphire (single-crystal alumina) were tested in 38% (20 M) HF at 90 °C (195 °F) for two weeks (Ref 50). All of the polycrystalline alumina had high corrosion rates, and most samples were consumed during the exposure. The silicate-based, glassy grain-boundary films were attacked. Sapphire had a 7 µm/yr (0.27 mil/yr) corrosion rate. High-purity alumina, doped with 500 ppm MgO and exposed in the same environment, had corrosion rates of less than 25 µm/yr (1 mil/yr) compared to samples without MgO that had 0.25 to 7.6 mm/yr (10 to 300 mils/yr) corrosion rates. The MgO acted to disperse silica and silicate into alumina grains so that HF could not attack them.

Various commercially available ceramic oxides, carbides, nitrides, and borides were exposed to 38% (20 M) HF at 90 °C (195 °F) for two weeks (Ref 51). The polycrystalline oxide ceramics, such as Al₂O₃, TiO₂, and ZrO₂, were severely attacked, but polycrystalline MgO corroded at only 10 µm/yr (0.4 mil/yr). The ceramics with the best resistance were sapphire and pure polycrystalline carbides such as SiC, B₄C, WC, and TiC. Notably, the pure SiC and alpha silicon carbides with no free silica or silicon ranged from no attack up to 5 µm/yr (0.2 mil/yr). However, commercial reaction-bonded and sintered SiC had corrosion rates of 0.18 to 3.8 mm/yr (7 to 150 mils/yr). Sapphire and pure polycrystalline carbides had the lowest corrosion rates.

Anhydrous Hydrogen Fluoride

Many metals and alloys have resistance to AHF, and most have high initial corrosion rates that diminish with the development of a surface film or scale of corrosion product. Therefore, the validity of short-term rates should be confirmed by longer tests. Table 16 lists data on the corrosion resistance of various metals in liquid AHF and AHF-hydrocarbon mixtures at temperatures of 15 to 90 °C (60 to 190 °F). Alloys have better resistance to AHF than HF, because AHF is less corrosive.

Carbon and Low-Alloy Steels

Liquid AHF is commonly handled in carbon steel railcars, storage tanks, and piping at temperatures up to 65 °C (150 °F) with velocity limited to 1.8 m/s (6 ft/s). At lower temperatures, steels can withstand higher liquid velocities. Gaseous AHF is less corrosive and is handled successfully at temperatures up to 200 °C (390 °F) with velocities up to 10 m/s (33 ft/s) and up to 300 °C (570 °F) in low-flow conditions. Figure 10 presents corrosion rates versus temperature for carbon steels exposed to AHF liquid and vapor. These data were generated in stagnant 100 h (average) tests. Steel vessels and piping can be passivated by exposure to AHF in stagnant vapor or liquid for approximately 24 h prior to velocity exposure. Carbon steels used for AHF storage for 40 years, at ambient conditions of 0 to 40 °C (30 to 105 °F), have lost less than 0.013 mm/yr (0.5 mil/yr). Even though metal loss is very low, there are two other problems caused by the reaction of AHF with iron. First, the corrosion product is approximately two times more voluminous than the corroded iron. The iron fluoride scale is hard, abrasive, and wedges between mating surfaces of pipe, flanges, and valve parts, which may lead to pipe joint leaks and inoperable valves. The fluoride scale also may flake off of surfaces and be carried into valves and pumps, causing wear. Second is that atomic hydrogen is generated and could lead to hydrogen damage of the carbon steel.

Residual Elements in Carbon Steels. Alloy steels often have higher corrosion than carbon steels in HF and AHF (Ref 18). Steels with high residual elements can have high corrosion rates in AHF, because the corrosion product layer is loose, porous, and nonprotective. Steels containing a sum of copper, nickel, and chromium, $\Sigma_{RE} > 0.2\%$, sometimes have increasingly high corrosion rates with increasing temperature. A fluorochemical plant had corrosion of

approximately 25.4 mm/yr (1000 mils/yr) on pipe, while carbon steel fittings on either side had only 0.89 to 1.27 mm/yr (35 to 50 mils/yr). The conditions were approximately 10% AHF and 90% organic at 80 °C (175 °F). Turbulent areas had higher corrosion loss. The pipe was ASTM A333 grade 9 with 0.81% Cu and 1.86% Ni. The fittings had no copper, nickel, or chromium. Table 17 data are from in-plant and lab corrosion studies in AHF with steels of varied compositions. This study indicates that steels with $\Sigma_{RE} > 0.2\%$ are susceptible to higher corrosion, and that rates increase with temperature and amount of AHF in the process.

Blistering and Cracking of Steels. Atomic hydrogen is formed when HF corrodes steel. Atomic hydrogen may either combine to form molecular hydrogen or be absorbed into the steel. Sulfides and arsenic in HF inhibit the formation of molecular hydrogen, promoting the entry of atomic hydrogen into the steel, where it may recombine at inclusion sites or laminations to form blisters or may migrate to dislocations in hardened steel to cause hydrogen embrittlement (Ref 8). Hydrogen may accumulate in closed vessels and cause unexpected leaks, ruptures, or reactions due to the increase in pressure (Ref 54). Hydrogen permeating through steel has accumulated in crevices created by support saddles, external attachments, slip-on flanges, reinforcing pads, and legs, causing bulges and cracking. Therefore, designs and procedures should consider ways of safely dealing with hydrogen. Carbon steel AHF vessels have experienced hydrogen blistering (Ref 55), hydrogen-induced cracking (HIC) (Ref 56), and hydrogen embrittlement. Hydrogen stress cracking has also occurred at hardened welds.

Steel Blistering. Hydrogen blistering is associated with oxide/sulfide inclusions that can mostly be prevented by specifying HIC-resistant steels. These are produced with low sulfur, calcium treatment, and vacuum degassing.

Table 16 Corrosion of metals and alloys in anhydrous hydrogen fluoride

Exposure for 6 to 40 days

Metal	Corrosion rate at temperature, °C (°F)							
	15–25 (60–80)		24–40 (80–100)		55 (130)		80–90 (180–190)

Source: Ref 52

Fine-grain practice (killed) steels are often preferred for lower-temperature service because of their improved notch toughness, particularly when normalized or quenched and tempered. Blistering occurs more readily in fine-grain practice steels, because the added aluminum forms clusters of Al_2O_3 particles that segregate in the center of the plate and form sites for hydrogen accumulation. Type II manganese sulfide inclusions, which predominate in killed steels, flatten out and also serve as sites for hydrogen accumulation. Steels for blistering environments should be hot rolled or annealed rather than cold rolled (Ref 57). Steels produced with only low sulfur are more resistant but not completely immune to hydrogen blistering. Both oxygen and sulfur are determinants for the distribution of oxide and sulfide inclusions in steels (Ref 58). NACE standard TM0284 (Ref 59) defines a test to determine steel resistance to hydrogen blistering and step-wise cracking. The HIC-resistant steels have good results in this test. NACE report 5A171 (Ref 3) has a discussion of the specifications and testing that may be applied to these types of steels.

Steel Cracking. Another effect of atomic hydrogen is cracking of carbon and alloy steels with hardness over HRC 22, or approximate tensile strength of 793 MPa (115 ksi) or higher. Susceptibility to cracking increases with residual

and applied stresses. In AHF, cold-worked carbon steels are susceptible to cracking as well as stress-oriented corrosion (Ref 53). The American Petroleum Institute's RP 751 (Ref 60) discusses recommendations for carbon equivalency and postweld heat treatment (PWHT) for steel less than or equal to 38 mm (1.5 in.) thick. A more detailed discussion on steps to minimize carbon steel susceptibility to cracking can be found in NACE standard RP0472 (Ref 61). As pointed out in the standard, stress-relief heat treatment, although desirable, will not necessarily reduce hardness, particularly that of high-manganese welds, and does not avoid the necessity for testing. Thick steel plates may cool rapidly when welded and may harden welds or HAZs. Higher-strength steels tend to have a harder weld HAZ that is typically where cracking is found after exposure to HF and AHF. Proper weld techniques, such as preheat, uphill welding of vertical seams, use of temper beads, and PWHT, are useful to reduce hardness of weld HAZ.

Austenitic Stainless Steels

Austenitic stainless steels have good resistance to liquid and vapor AHF up to 100 °C (210 °F). In pure liquid AHF at ambient

temperatures, austenitic stainless steel types 304, 304L, 316, 316L, CF8M, and CF3M have been used for pumps, valves, piping, storage tanks, and transportation equipment. However, both type 304 stainless steel and carbon steel have been known to fail by direct impingement of AHF steams. Corrosion rates for type 304 stainless steel and carbon steel exposed in AHF vapor are shown in Fig. 11. Type 304 stainless steel corrosion rates increase with temperature above 100 °C (210 °F), and the corrosion rates are more erratic above 100 °C (210 °F) in tests and service.

Cracking. A cold-worked type 303 stainless steel fastener failed rapidly in a HF plant. Cold-worked type 304 stainless steel fasteners (ASTM A193, grade B8, class 2) had few failures. The failed fasteners were magnetic. Alpha-martensite is formed when alloys such as types 301, 303, and 304 stainless steels are cold worked (Ref 8), thus increasing their magnetic permeability. Increasing α -martensite content increases susceptibility to hydrogen embrittlement (Ref 62) and corrosion in nonoxidizing acids (Ref 63). Magnetic permeability may be tested by Severin gage (12.5 maximum) to sort those that are magnetic. Some users specify type 316 stainless steel that is metallurgically stable and does not develop α -martensite.

Fig. 10 Corrosion rates of carbon steels in static anhydrous hydrogen fluoride (AHF) liquid and vapor. These data emphasize that liquid AHF is more corrosive than vapor, and that carbon steels have acceptable corrosion in static AHF at 300 °C (570 °F). The critical point occurs at 188 °C (370 °F) and 64.88 bars (941 psia). Source: Ref 53

Fig. 11 Corrosion rates for type 304 stainless steel and carbon steel in static anhydrous hydrogen fluoride vapor. Type 304 corrosion rates are erratic above 100 °C (210 °F).

Cold-worked type 316 stainless steel tubing cracked in AHF at 40 °C (105 °F) (Ref 53). These were transgranular and intergranular cracks, with initiation on the AHF side. This was classified as AHF environmental stress cracking. Another case of AHF environmental cracking occurred in type 316L stainless steel cold bent piping after two years. The process contained organics, AHF, and trace anhydrous HCl (AHCl) at -29 °C (-20 °F). Intergranular cracking was observed in elbows but not in piping or welds. There was no sensitization. Cold-worked type 316L stainless steel is susceptible to intergranular SCC in AHF with traces of AHCl (Ref 64).

Nickel-Rich Austenitic Stainless Steels

In liquid AHF service, high-nickel austenitic stainless steels with chromium, molybdenum, and copper, such as alloys G3, G30, 20, and 825, have excellent corrosion resistance up to at least 125 °C (255 °F). Their resistance to AHF in flowing conditions makes these alloys useful for applications such as pumps, valves, and heat-exchanger tubing. The preferred material for cast pumps and valves for AHF service is CN-7M casting alloy (Ref 18).

Weld Corrosion. Alloy 20, 825, G, and G30 welds are susceptible to corrosion when exposed to AHF. Autogenous welds in alloy 20 tubing had a rate of 0.254 mm/yr (10 mils/yr) versus 0.0254 mm/yr (1 mil/yr) on the base metal when exposed to 10% AHF, 1% Cl₂ and chloro-fluorocarbons at 95 °C (205 °F) (Ref 53). Weld attack of these alloys is due to weld alloy segregation as well as the detrimental effect of reactive metals such as niobium, tantalum, and titanium. These reactive metals may be alloyed in the base metal as well as welding consumables.

Cracking. Alloys 20, 825, and G30 have given satisfactory service in AHF environments that have SO₂; air or oxygen has caused SCC of alloy 400. However, there have been cases of in-service SCC of these nickel-rich austenitic stainless steel alloys when exposed to AHF and cupric fluoride. These were downstream of copper-bearing alloys.

An alloy 20 cold-formed dished head on a pressure vessel cracked within a week of exposure to AHF. The cracking was transgranular and concentrated at the knuckle radius where the cold deformation was greatest. A replacement head that was annealed after forming gave good service.

Nickel and Nickel Alloys

Corrosion data for alloys 200, 400, and 600 in AHF are presented in Table 16. Nickel alloys have excellent corrosion resistance to AHF. Alloy 200 is used for rupture discs in AHF storage tanks and railcars at ambient temperatures and for pipe and equipment to handle AHF liquid and vapor from -40 to 600 °C (-40 to

1110 °F). Alloys 600, C22, and C276 are used in valves, piping, and tubing for AHF up to at least 149 °C (300 °F). Alloy 600 has been used in valves and other equipment in place of alloy 400 to avoid possible SCC. It is the most widely used alloy for hot HF vapors, combining excellent chemical resistance and good metallurgical stability. Alloy 400 is used up to at least 149 °C (300 °F) in AHF alkylation service where process conditions are air-free.

Cracking. Alloys 400 and 500 fail by SCC in AHF after opening systems to air for maintenance or inspections. General practice in AHF alkylation service is to stress relieve alloy 400 at 621 °C (1150 °F). However, nickel alloy and HF manufacturers recommend stress relief at 705 °C (1300 °F) for 2 h to avoid SCC of alloy 400. This is a prudent practice in systems where HF-exposed metal is rarely exposed to oxygen. However, for alloy 400 equipment that will be exposed to AHF and oxygen, stress relief may reduce the potential for SCC, but it will not prevent intergranular corrosion (Ref 53). In such cases, other alloys should be considered. Nickel alloys may be susceptible to SCC when CuF₂ is present in AHF. There are reports of SCC in AHF for various nickel alloys that were downstream from copper-containing alloys.

Environmental stress cracking of alloy 600 has occurred in AHF at 135 °C (275 °F) and in AHF with 5% Cl₂ at 100 °C (210 °F). In both cases, corrosion loss was nil, and transgranular cracking occurred within days of initial service. Cracking was found only at the knuckle radius of cold-formed, dished heads (Ref 53). Associated equipment with annealed alloy 600 had no cracking in the same environments. To prevent cracking in AHF, alloy 600 should be solution annealed after cold forming.

Nickel and Nickel Alloys in High-Temperature AHF and HF

Resistance of nickel alloys in high-temperature HF and AHF is dependent on the formation of thin, adherent, protective metal fluoride films. Nickel fluoride and molybdenum fluoride films are relatively stable compared to other nickel halides and are protective to the extent that their vapor pressure is less than or equal to 10 Pa (10⁻⁴ atm), and their melting point is higher than the service temperature (Ref 65). Corrosion is only one mode of high-temperature degradation in AHF/HF. Internal degradation also occurs, due to permeation of high-temperature AHF/HF, which affects corrosion behavior and mechanical properties. Permeability is a product of fluoride diffusivity and solubility in metal. Chromium, niobium, tantalum, titanium, and iron are detrimental to fluorination resistance because they form high-vapor-pressure and low-melting-point metal fluorides that increase corrosion susceptibility of nickel-base alloys. These elements also increase internal damage. Corrosion data presented for metals in high-temperature AHF/HF are from tests of a few hours to a few days, which

is appropriate for ranking relative corrosion resistance and observation of short-term physical changes in the metal. Above 400 °C (750 °F), some high-strength nickel alloys undergo long-term metallurgical changes, such as aging or long-range ordering, thus increasing hardness, reducing fracture toughness and creep ductility, and increasing susceptibility to hydrogen embrittlement or corrosion. Alloys 200, 201, and 600 are relatively unaffected.

Alloying Element Influence on Corrosion in High-Temperature AHF. Corrosion data for various metals in AHF at 500 to 600 °C (932 to 1112 °F) from 4 to 15 h tests are found in Table 18, and from 36 h tests in Table 19. Corrosion data for pure nickel in Ar-5% AHF at 1000 °C (1832 °F) from 15 h tests are given in Table 20, and from 15 h tests in Table 21. From Table 18, the lowest corrosion rates were observed for copper and nickel alloys 200, 400, and 600, while the highest corrosion rates were for iron-base alloys. The highest corrosion rates were associated with high chromium and niobium content (309, 310, and 347). Table 19 presents some of the same alloys but with longer exposure and lower corrosion rates; note that alloys C and B (UNS N10002 and N10001) with molybdenum had low corrosion rates. Exposed nickel alloys in AHF at 650 °C (1200 °F) with more chromium had higher corrosion rates and higher internal fluoride formation in AHF (Ref 69). In 10 h exposures to AHF at 850 °C

Table 18 Corrosion of metals and alloys by gaseous anhydrous hydrogen fluoride at elevated temperatures

(1560 °F), nickel, cobalt, copper, and molybdenum had lower corrosion rates than iron, chromium, niobium, and tantalum (Ref 70). In Ar-5% AHF exposures at 1000 °C (1830 °F), high-purity nickel alloy 227 (UNS N02270) had the lowest corrosion rates and had no measurable internal fluoridation (Ref 68). Alloys based on nickel and cobalt had higher corrosion rates than pure nickel and exhibited internal fluoride formation. Nickel-molybdenum alloys had lower corrosion rates and internal fluoride formation than other alloys among these observations. Extensive internal fluorides were found in alloys 600, 617 (UNS N06617), and 602CA (UNS N06025).

Water and Oxygen Influence on High-Temperature AHF and HF Corrosion. For some metals, HF and water is less corrosive than AHF at high temperatures. Corrosion data are presented in Table 22 for various alloys in 5% HF, 8% O₂, 15% H₂O (balance as CO₂ and N₂) for 100 and 155 h exposures at 450 °C (842 °F) (Ref 22). These low corrosion rates may be due to water vapor and oxygen promoting a protective metal oxide film. Nickel-chromium alloys exposed to HF with steam at 650 °C (1200 °F) produced a chromium-oxide-rich surface scale with fluorides in the underlying alloy; also, there was an internal corrosion product network with Cr₂O₃ and chromium fluorides (CrF₂ and CrF₃) (Ref 69). Table 23 data are for alloys 200 and 400 exposed in 50% HF and 50% steam for 4 to 15 h from 550 to 750 °C (1022 to 1382 °F). The trend indicates increasing corrosion with temperature. From a comparison of data in Table 18 to AHF data in Table 23, steam in HF increases corrosion of Ni 200 but decreases corrosion of alloy 400 at 600 °C (1112 °F). From 10 h exposures to HF-50% H₂O at 850 °C (1560 °F), nickel, cobalt, copper, iron, chromium, and tantalum had lower corrosion rates than in AHF, while molybdenum had higher rates (due to oxide formation) (Ref 70). These alloys were examined after 50 h exposures to 90% HF and 10% steam at 850 °C (1560 °F), and types 304, 310, and alloy 800 (UNS N08800) had corrosion rates of 100 to 130 mm/yr (4000 to 5000 mils/yr); thick, brittle corrosion products; and a porous metal matrix. Alloy 600 had a corrosion rate of 23 mm/yr (900 mils/yr), with external iron oxide scaling and internal precipitation of chromium fluorides. Alloy 625 had a corrosion rate of 6.7 mm/yr (265 mils/yr), with an external scale rich in niobium and oxygen and internal chromium fluoride precipitation.

Welds. Weld deposits of alloys 62 (1.5 to 3% Nb; UNS N06062), 82 (2 to 3% Nb; UNS N06082), 132 (1.5 to 4% Nb; UNS W86132), and 182 (1 to 2.5% Nb; UNS W86182) were exposed to AHF at 350 to 400 °C (660 to 750 °F) for two weeks. These welds had corrosion rates of 0.25 to 0.58 mm/yr (10 to 23 mils/yr), while alloy 600 was 0.05 mm/yr (2 mils/yr) (Ref 53). In-service weld attack was noted in AHF, starting at 150 °C (300 °F) and increasing with temperature. At 350 °C (660 °F), weld corrosion rates were 0.4 to 0.6 mm/yr (16 to 24 mils/yr) versus rates on

alloy 600 of 0.025 mm/yr (1 mil/yr). Weld corrosion deposits were higher in niobium, tantalum, and titanium than the weld metal.

Cracking. Table 22 includes a report of SCC of alloy 600 in 5% HF, 8% O₂, 15% H₂O

(balance as CO₂ and N₂) at 450 °C (842 °F). This was a very low-corrosion-rate environment, and cracking occurred within 100 h on U-bend samples that were not initially cold worked but subject to strain when bent.

Copper Alloys

Table 16 is static-condition corrosion data for copper, copper-nickel, brass, and bronze alloys in AHF. Copper-nickel alloys 90-10 (UNS C70600) and 70-30 have been successfully employed for heat-exchanger tubing because of their corrosion resistance in flowing AHF (Ref 3). Copper-nickel alloys have also been used for bolting in AHF in lieu of alloy 400 because of their SCC resistance. Copper tubing has been used at ambient temperature for AHF liquid and vapors at low velocities.

Precious and Other Metals

Silver, gold, platinum, tungsten, and molybdenum resist corrosion in AHF. Tungsten and molybdenum are used for special parts in valves and equipment that may be fabricated without welding. Silver, despite its higher cost compared to other materials, has been used in AHF services such as stills, heating coils, condensers, rupture disks, and pressure diaphragms. However, silver in AHF service has high corrosion rates when also exposed to oxygen, hydrogen sulfide, or sulfur contamination. Gold, platinum, and palladium were exposed to Ar-5% AHF at 1000 °C (1830 °F) for 15 h (Ref 68). Gold had no corrosion, platinum had a corrosion rate of 0.03 mm/yr (1.1 mil/yr), and palladium had a weight gain, but the appearance was unchanged.

Aluminum and its alloys have not been employed in AHF service, even though they have some resistance, as noted in Table 16, because they experience very high corrosion rates in HF. Hydrofluoric acid solutions are formed during water exposure, which would be required when washing out equipment for inspections and maintenance.

Nonmetals

Thermoplastics. Fully fluorinated plastics are resistant to AHF up to and above the boiling point. Fully fluorinated plastics, such as PFA, PTFE, FEP, and MFA, do not lose strength, swell, crack, embrittle, or undergo chemical attack by AHF. However, AHF will permeate through fully fluorinated plastics, and the rate of permeation increases with increasing temperature, concentration, vapor pressure, and with decreasing liner thickness. More information is presented in the HF section about thermoplastics in this article.

Elastomers. Manufacturers should be consulted for guidance on the best compounds, fillers, and cures for specific AHF service conditions. Only a limited group of fluoroelastomers, designated FKM, in accordance with ASTM D 1418, have resistance to AHF, and these generally are carbon-filled and peroxide-cured. Perfluoroelastomers designated FFKM, in accordance with ASTM D 1418, generally have resistance to AHF at ambient temperatures and above. There are, however, performance

differences among the various grades of FFKM (Ref 2). The higher the fluorine content of the elastomers, generally the better the chemical resistance in AHF.

Carbon and graphite (both with low ash) resist AHF. Flexible graphite (low ash or nuclear grade) has been used for gaskets and packing materials in AHF services. Carbon-carbon composites have excellent resistance to AHF; however, their use is limited to internal components because they are permeable. Two grades of graphite (with <5 and 700 ppm total ash) were exposed to Ar-5% AHF for 15 h at 1000 °C (1830 °F) (Ref 68). Both samples had no weight change and appeared unchanged.

Alumina (>99.7% purity), sapphire, and ruby have been used in instruments and analyzers in AHF services. Alpha silicon carbide (fully reaction bonded with no free silicon) has been used in AHF for pump bearings and heat-exchanger tubing.

ACKNOWLEDGMENTS

The author acknowledges E.I. DuPont for the opportunities to learn about corrosion by HF and AHF and to prepare this article. Appreciation goes to Paul Crook of Haynes International for being so responsive in providing corrosion data on nickel alloys. Thanks to Jeffrey M. Chandler, Amy Anderson-Maifeld, Brian J. Saldanha, and Larry D. Schwarz for their comments and suggestions.

Corrosion by Chlorine

E.L. Liening, The Dow Chemical Company

CORROSION OF METALS by dry liquid chlorine, dry gaseous chlorine, moist chlorine, selected mixed gases with chlorine, and chlorine-water is considered in this article. Also considered are nonmetals used with chlorine and those materials of construction frequently used in handling chlorine.

Chlorine is a yellow-green halogen gas with an atmospheric boiling point of -24°C (-11°F) and a liquid density of 1.468 g/cm^3 at 0°C (32°F). Chlorine is soluble in water, forming a highly oxidizing hypochlorous acid solution. Solubility of chlorine ranges from 10.46 g/L of water at 0°C (32°F) to 6.4 g/L at 25°C (75°F).

Materials (including nonmetals) used in chlorine manufacturing are reviewed in Ref 1 and 2. Reference 3 is a good source for references on corrosion by chlorine published prior to 1976. The Chlorine Institute (Ref 4), a trade association of chlorine manufacturers, also provides information on handling chlorine.

Handling Commercial Chlorine

Commercial chlorine is widely used for bleaching and water treatment. It is typically handled as a dry liquid (less than 40 ppm water) under pressure in carbon steel tanks. Piping is commonly carbon steel. Cast iron is not considered suitable for handling commercial chlorine because of its susceptibility to brittle failure. Equipment containing cast components, such as pumps and valves, is typically ductile iron or alloy 400 (UNS N04400). Valve trim commonly includes alloy 400 seats and alloy C276 stems. Gaskets are often spiral-wound alloy 400 with polytetrafluoroethylene (PTFE) filler (Ref 1–3).

Equipment handling commercial chlorine must be free of water, organic contamination, and metal shavings to avoid unwanted exotherms and possible ignition events. Cleaning guidelines for piping systems handling commercial chlorine are given by The Chlorine Institute (Ref 4). Ultraviolet lights are sometimes used to inspect for organic contamination before exposing equipment to liquid chlorine.

Chlorine lines that are refrigerated below 0°C (32°F) for extended times may become covered in ice. Alloy 20 (UNS N08320) valves are used in

such conditions, and valve bonnet bolting should be adequately corrosion resistant to withstand moist chlorine gas that accumulates under the ice as the result of fugitive emissions from the valve. This may require alloy C276 or similar nickel-chrome-molybdenum alloy bolting.

Dry Chlorine

Dry chlorine is not corrosive to steels, stainless steels, or nickel alloys at ambient temperatures. It is commonly shipped and handled in carbon steel equipment, with higher-alloy materials such as nickel, Monel 400, and Hastelloy C usually used for critical parts. Valves are frequently steel, with Monel 400 or Hastelloy C trim and stem. Steel is usable up to approximately 150°C (300°F) and possibly higher under certain conditions. Stainless steels are usable up to approximately 300°C (570°F), and nickel is commonly used up to approximately 500°C (930°F). Alloy 600 (UNS N06600) or low-carbon nickel is often used at temperatures where graphitization may occur. Moisture will greatly accelerate attack on any of these materials, with the additional danger of stress-corrosion cracking (SCC) of stainless steels.

Iron and Steel. Eight-hour tests showed corrosion rates for steel to be below 0.0025 mm/yr (0.1 mil/yr) at up to 250°C (480°F), but ignition occurred at 250°C (480°F) (Ref 5). A slightly lower ignition temperature was reported for 16 and 20 h tests (Ref 6). Ignition of steel wool (grade 00) occurred at temperatures as low as 185°C (365°F) (Ref 5).

A maximum-use temperature for steel is given as 205°C (400°F) in Ref 6 and 7, but the discussion in Ref 7 suggests that a prudent maximum temperature may be nearer 150°C (300°F) because of exotherms from reaction with grease-contaminated equipment. For grease-free and properly cleaned equipment, however, a maximum-use temperature of 200°C (390°F) may be acceptable.

Tests with various irons and steels in flowing chlorine indicated that ignition occurs at lower temperatures for steels with higher alloy contents, especially carbon (Ref 8, 9). Ignition at temperatures as low as 220°C (430°F) was found for iron containing 0.3% C and 6% other

alloy content. This probably accounts for the lower use temperature for cast iron versus steel given in Ref 6. Iron alloys with silicon contents in the 10 to 15% range, however, reportedly resisted attack by dry chlorine (Ref 10, 11), but their poor impact properties limit practical applications in such critical service.

Below 250°C (480°F), the presence of oxygen and moisture had little effect on iron chlorination rates (Ref 12). Because iron is attacked less rapidly by hydrogen chloride than chlorine, the presence of hydrogen chloride in dry chlorine should have little effect on iron chlorination rates. In practice, however, the use of steel is avoided where moisture may be present.

Table 1 indicates corrosion rates and suggests upper temperature limits for use of metals in dry chlorine, based on 2 to 20 h tests (Ref 6). The temperature limits for many of the alloys correspond to higher corrosion rates than may usually be tolerated for expensive alloys. The rates shown, however, are in most cases higher than those that would occur in prolonged exposures. This is because, for most of the alloys, passivation occurs by the formation of a metal chloride film, after which corrosion decreases rapidly. In many cases, corrosion at higher temperatures is roughly proportional to the vapor pressure of the particular metal chlorides formed. Suggested upper design limits for steel and some other alloys in dry chlorine are shown in Fig. 1, based on corrosion rates of approximately 0.08 mm/yr (3 mils/yr) for tubes and internals and 0.5 mm/yr (20 mils/yr) for vessels and pipes. Similar design guidelines are discussed in Ref 14 and 15.

Aluminum. Care must be taken when evaluating results for aluminum, because the protective aluminum oxide film may delay the onset of corrosion. In one study, there was a 5 h delay before reaction in dry chlorine at 500°C (930°F) (Ref 8). Aluminum was reported to be usable up to approximately 120°C (250°F) (Ref 6), and moisture in dry chlorine at room temperature increased attack (Ref 16). This is supported by the work documented in Ref 17 and is attributable to condensation. At higher temperatures (130 to 630°C , or 265 to 1165°F), the presence of water was reported to decrease attack on aluminum (Ref 18).

Copper. A maximum-use temperature of 205°C (400°F) was suggested for copper in dry

chlorine (Ref 6). Ignition of copper was observed at temperatures as low as 260 to 300 °C (500 to 570 °F) at high velocities (Ref 19). Ignition occurred at 290 to 310 °C (555 to 590 °F) at a velocity of 250 mL/min, and no ignition occurred at 40 mL/min (Ref 12). The same researchers reported that below 200 °C (390 °F), the presence of oxygen and water vapor accelerates attack on copper, while above 250 °C (480 °F), they reduce the rate of attack and move the ignition temperature to near 350 °C (660 °F) (Ref 12, 20).

Stainless Steels. Austenitic stainless steels were shown to be significantly more resistant to

dry chlorine than steel, aluminum, or copper (Ref 6, 8). Type 304 and type 316 stainless steels may be used up to 300 °C (570 °F). Moisture was reported to accelerate attack below 370 °C (700 °F) but to exert little effect or even decreased attack above the temperature (Ref 6, 18). The presence of moisture also increases the possibility of SCC.

Nickel and Nickel Alloys. Nickel 200 and nickel-base alloys show excellent resistance to dry chlorine, as indicated in Table 1. The good performance of nickel was supported by data in Ref 21 for tests in chlorine at a pressure of 13.2 kPa (0.13 atm) and in Ref 8 in flowing

chlorine. However, the reports indicated higher corrosion rates (2.4 and 2 mm/yr, or 95 and 81 mils/yr) for nickel at 525 to 540 °C (975 to 1000 °F) than the study described in Ref 6. A temperature of 500 °C (930 °F) seems a wise upper limit for routine use of nickel in dry chlorine.

Water vapor was found to increase attack on nickel below 550 °C (1020 °F) but had little effect above that temperature (Ref 18). Between 425 and 760 °C (795 and 1400 °F), graphitization of Nickel 200 may occur, and a low-carbon version of nickel with a maximum of 0.02% C is normally used. When sulfur compounds are present, alloy 600 is often substituted for nickel to avoid intergranular attack.

The data given in Table 1 indicate that Inconel 600 and nickel-molybdenum alloy B perform nearly as well as nickel in dry chlorine, and Ni-Cr-Mo alloy C somewhat less well. Chromel A and alloy 400 perform much better than stainless steels but not as well as the other alloys mentioned previously. Cast Alloy Casting Institute (ACI) alloy CW-12M (Ni-18Cr-18Mo) was reported to corrode in dry chlorine at 0 to 60 °C (32 to 140 °F) at approximately the same rate as Ni-Cr-Mo alloy C (Ref 22, 23).

Monel 400 is commonly used as trim on valves, but it should be used with care in refrigerated systems. Water vapor in chlorine at temperatures below the dewpoint is corrosive to a wide variety of nickel, nickel-copper, nickel-chromium-iron, and nickel-chromium-molybdenum alloys (Ref 24).

Other Metals. Limited information on the performance of various other alloys in dry chlorine is also available. Magnesium was found to perform as well as Chromel A and actually better than alloy 400 (Ref 6). A maximum-use temperature of 455 °C (850 °F) was suggested, but use of magnesium in chlorine is not widespread.

Lead was found to be resistant in dry chlorine up to 275 °C (525 °F) (Ref 25). Average corrosion rates for lead in dry flowing chlorine were reported as 0.06 mm/yr (2.4 mils/yr) at 200 °C (390 °F), 0.13 mm/yr (5.1 mils/yr) at 250 °C (480 °F), 0.14 mm/yr (5.5 mils/yr) at 275 °C (525 °F), 1.5 mm/yr (59 mils/yr) at 295 °C (565 °F), and 2.5 mm/yr (98 mils/yr) at 310 °C (590 °F) (Ref 9, 18).

Unalloyed zirconium corrodes at less than 0.13 mm/yr (5 mils/yr) in dry chlorine near room temperature but is not resistant in wet chlorine (Ref 22, 23, 26–28). Reactor-grade zirconium tubing was reported to stress-corrosion crack in 0.01 mg/cm³ of chlorine gas at 360 to 400 °C (680 to 750 °F) (Ref 29).

Titanium was found to ignite in dry chlorine at temperatures as low as –18 °C (0 °F) (Ref 22, 23, 30, 31). However, small amounts of moisture in chlorine can passivate titanium.

Niobium suffered no attack in dry chlorine up to approximately 200 °C (390 °F) (Ref 32).

Tantalum performs well in dry chlorine up to 250 °C (480 °F) (Ref 33, 34). Attack on tantalum was shown to begin at 250 °C (480 °F), to be

Table 1 Approximate temperatures at which the indicated corrosion rates occur in dry chlorine

Alloy	Temperature for corrosion rate, mm/yr (mils/yr)											
	0.76 (30)		1.5 (60)		3 (120)		15 (600)		30 (1200)		Maximum(a)

Fig. 1 Design guidelines for use in dry chlorine. Source: Ref 13

violent after 35 min at 450 °C (840 °F), and to be instantaneous at 500 °C (930 °F) (Ref 35). This is consistent with the data given in Ref 18. Pitting of tantalum was reported in a mixture of dry chlorine and anhydrous methanol at 65 °C (150 °F), presumably caused by the presence of halogenated HCOOH contamination (Ref 29).

Nonmetals. The use of carbon steel in dry chlorine generally makes it unnecessary to use the more costly nonmetallic alternatives. Keeping that in mind, the following comments can be made about nonmetallics that sometimes find applications in dry chlorine service.

Glass-lined steel is resistant to dry chlorine as either the liquid or gas, although gaskets can be short-lived. The common PTFE envelope-style gasket for glass-lined steel is susceptible to permeation of chlorine through the PTFE envelope, followed by degradation of the filler material.

PTFE equipment can be used at temperatures up to 150 °C (300 °F) if adequate consideration is given to chlorine permeation effects. Examples are PTFE-lined pipe and vessels and wire-reinforced PTFE hose. Particularly for the hose, care should be taken to limit exposure so that the hose burst pressure is not reduced by corrosion of the metal reinforcement caused by permeated chlorine. Such hoses should be removed from service before burst pressure is affected. Note that this may be before visible indications of degradation are apparent. The practical problem of knowing when to decommission a hose adversely affects the practicality of this option.

Fiber-reinforced pipe and vessels can be used in dry chlorine gas if the appropriate resins, reinforcements, and designs are used. Polyester resins are generally not suitable (Ref 2), but some formulations of vinyl-ester resins are usable up to 121 °C (250 °F) (Ref 36). Consult the manufacturers for design and fabrication guidelines for these materials in this service.

Polyvinylidene fluoride (PVDF)-lined equipment can be used up to 93 °C (199 °F), with appropriate care taken to account for permeation. Permeation is significantly less than for PTFE, but it cannot be ignored. Monolithic PVDF equipment is available but should be used only with careful consideration of piping and other secondary stresses that could break nozzles and joints. Most users opt for more robust systems because of the hazard associated with chlorine releases.

Polypropylene, another common lining material for pipe and vessels, is not reliably resistant to dry chlorine and should not be used in this service.

Polyethylene, a common monolithic pipe and vessel material, is only marginally resistant to dry chlorine and is generally avoided.

Graphite is a common gasket material. It is not suitable in liquid chlorine, because it reacts directly with it to form an interstitial compound (Ref 2). However, so-called flexible graphite is free of fillers and impregnates and can be used in wet and dry chlorine gas.

Elastomer performance is summarized in Ref 2 for both dry and wet chlorine. Natural, butyl,

silicone, and nitrile elastomers are reported as not suitable for service. Ethylene propylene rubber, ethylene-propylene-diene monomer, and chlorosulfonated polyethylene (Hypalon, Dupont Dow Elastomers) are reported as suitable up to 65 °C (150 °F). Fluoroelastomers and perfluoroelastomers are generally suitable to higher temperatures. As with most elastomeric applications, actual performance is highly dependent on the circumstances of use. Dynamic versus static conditions and trapped versus open-seating geometries are particularly important.

Refrigerated Liquid Chlorine

Refrigerated liquid chlorine can be handled in steel, but special care should be taken at potential leak sites, such as at valves and nonwelded fittings. Because the chlorine is refrigerated, pipelines and associated equipment become encased in ice formed from the moisture in the air. Chlorine from even small leaks is then trapped beneath the ice, forming wet chlorine gas that is corrosive even at low temperatures. Therefore, alloy 20 materials are often used for valves and other fittings in refrigerated liquid chlorine equipment.

Similarly, ordinarily nonwetted parts, such as bonnet bolts in valves, are typically replaced by more resistant alloys. Nickel-copper alloys, such as alloy 400, have been used, but they are sensitive to oxidizing corrosives. Figure 2 shows an example of corrosion of alloy 400 bonnet bolts. Chlorine had leaked along the valve stem and was trapped beneath the ice, where it became wet and very corrosive. Nickel-chromium-molybdenum alloys, such as alloy C276, are used in order to avoid this type of attack on critical components such as bonnet bolts.

High-Temperature Mixed Gases

Several investigations were conducted on alloys in high-temperature mixed gases of chlorine, oxygen, and argon. Various alloys were tested in an atmosphere of argon, 20% O₂, and 2% Cl₂ at 900 °C (1650 °F) for 8 h (Ref 37). Alloy 214 performed the best, with metal loss of less than 0.025 mm/yr (1 mil/yr). Alloy R-41 (UNS N07041) was the next best performer, followed by Inconel 601 and 600, type 310 stainless steel, and alloy 625. Hastelloy S was less resistant than the aforementioned group, followed by alloy 800H, alloy X, alloy C276, and alloy 188. Longer-term tests in a similar environment yielded the following in order of performance: alloys 214, 601, R-41, X, C276, and 625.

Corrosion in argon-oxygen-chlorine mixtures was investigated on a more basic level (Ref 38). Work was performed in environments containing argon, 20% O₂, and 0.25% Cl₂ at 900 to 1000 °C (1650 to 1830 °F) and in air and 2% Cl₂ at the same temperatures (Ref 39, 40). A report

on the corrosion at 260 to 425 °C (500 to 795 °F) of a variety of engineering alloys considered for use in a waste heat recovery system for a chlorinated hydrocarbon incinerator is given in Ref 41.

Moist Chlorine

Many industrial chlorine environments contain substantial water, particularly those in chlorine manufacture prior to the drying operation. Wet chlorine gas is extremely corrosive at temperatures below the dewpoint, because the condensate is a very acidic and oxidizing mixture. One of the most commonly used metals for wet chlorine service is titanium, especially for wet chlorine compressors. Titanium is perfectly passive if there is enough water in the chlorine, but it ignites if there is not enough. With sufficient water, titanium is resistant up to at least 175 °C (345 °F) and probably higher. Wet chlorine gas can be handled at room temperatures with stainless steels similar to alloy 20 if condensation is not too great and if corrosion

Fig. 2 Monel 400 bonnet bolt extensively corroded by chlorine gas trapped beneath ice covering a valve in liquid chlorine service

rates up to 1.3 mm/yr (50 mils/yr) are tolerable. Alloy C276 is suitable to somewhat higher temperatures, and niobium or tantalum is required at even higher temperatures.

Iron and Steel. The response of iron-base alloys to moisture in chlorine depends on the temperature range and particular class of alloys. At practical-use temperatures, small amounts of moisture and oxygen were reported to have little effect on iron chlorination rates; these contaminants were found to reduce chlorination rates above 300 °C (570 °F) (Ref 8, 20, 42). In practice, steel is generally avoided in any service where chlorine gas may collect water vapor.

Stainless Steels. Moisture has a significant effect on the corrosion of type 304 stainless steel in chlorine, as indicated in Ref 6, which documents tests conducted on type 304 stainless steel in chlorine containing 0.4% H₂O. Rates of approximately 30.5 mm/yr (1200 mils/yr) were found at 40 °C (105 °F), versus an estimated 0.3 mm/yr (12 mils/yr) at 100 °C (210 °F) in dry chlorine. Corrosion in wet chlorine decreased with increasing temperature until approximately 370 °C (700 °F), at which point the corrosion was approximately 4.6 mm/yr (180 mils/yr) and the effect of the moisture disappeared. The detrimental effect of moisture at low temperatures is believed to exist for chromium and austenitic stainless steels in general. Several alloys were tested in water-saturated chlorine gas for 6 weeks at room temperature (Ref 43). The results (Table 2) show substantially higher rates than in dry chlorine. The data support the view that moisture in room-temperature chlorine gas increases corrosion rates of stainless steels, including cast stainless steels.

Aluminum. Aluminum alloy 1100 is more readily attacked by wet than dry chlorine at room temperature, especially if condensation is present. At temperatures above 130 °C (265 °F), however, the presence of moisture greatly reduces corrosion on aluminum. Data from Ref 18 (Table 3) show that larger amounts of water more effectively reduce corrosion on aluminum. Aluminum appears to be usable to 130 °C (265 °F) at 0.06% H₂O, 200 °C (390 °F) at 1.5% H₂O, and 545 °C (1015 °F) at 30% H₂O.

Copper and copper alloys were found to suffer accelerated attack in chlorine gas saturated with water vapor (Ref 44). Copper alloys do not have adequate corrosion resistance for practical use in moist chlorine at temperatures above

200 °C (390 °F). Water vapor at room temperature was shown to accelerate attack on copper and copper alloys (Ref 45). The same effect was reported on copper at temperatures below 200 °C (390 °F) (Ref 12). Above 250 °C (480 °F), however, water vapor and oxygen in chlorine was reported to reduce attack of copper and to move its ignition temperature from approximately 300 °C (570 °F) to approximately 350 °C (660 °F) (Ref 12, 20).

Nickel and nickel alloys are adversely affected by the presence of moisture in chlorine at temperatures up to their maximum-use temperatures in dry chlorine. Water vapor at 1.5% was found to double the reaction rate between chlorine and nickel, while 30% H₂O increased the rate from 2 to 20 times (Ref 12, 18). Above 550 °C (1020 °F), moisture was reported to have little effect, but the rates at that temperature even in dry chlorine make nickel marginal.

Alloy C276 corrodes 2 to 1000 times faster, and Chlorimet 3 (62Ni-18Cr-18Mo) 100 to 1000 times faster, in wet chlorine than in dry. Numerous other nickel, nickel-copper, nickel-chromium-iron, and nickel-chromium-molybdenum alloys are also reported to suffer greatly accelerated attack by wet chlorine at such temperatures.

Titanium is well known for its resistance to corrosion by wet chlorine and is widely used in various chlorine-manufacturing equipment, such as compressors that are exposed to wet chlorine. However, a minimum quantity of water is required to maintain the passivity of titanium. The amount of water required at temperatures between 25 and 175 °C (75 and 350 °F) was found to depend on chlorine pressure, temperature, flow rate, purity, and degree of surface abrasion of the titanium (Ref 30). Figure 3 shows a general guideline for water content needed to maintain passivity of commercial-purity titanium in chlorine at temperatures to 105 °C (220 °F).

Crude cell chlorine tested under static conditions required approximately 0.5% H₂O at 125 °C (225 °F) and 1.2% H₂O at 175 °C (350 °F) (Ref 30). Less water was required at flow rates above 0.15 m/s (0.5 ft/s). Pure

(99.5%) chlorine requires relatively more water: approximately 0.93% at room temperature and 1.5% at 200 °C (390 °F) under static conditions.

Other Metals. Relatively limited information is available for other materials. Unalloyed zirconium was found to corrode in wet chlorine at a rate of 2 mm/yr (80 mils/yr) at 15 °C (60 °F) (Ref 23) and 4.9 mm/yr (192 mils/yr) at 25 °C (75 °F) (Ref 27). It also corroded at over 1.3 mm/yr (50 mils/yr) in room-temperature chlorine containing 0.3% H₂O (Ref 28).

Niobium was found to be resistant to wet chlorine at up to 100 °C (210 °F) and tantalum at up to 150 °C (300 °F) (Ref 11, 34, 46, 47).

Tantalum reportedly performed well in chlorine plus 1.5% H₂O at up to 375 °C (705 °F) and in chlorine plus 30% H₂O at up to 400 °C (750 °F) (Ref 35). However, other studies indicated higher rates under these conditions (Ref 18). Another source reported corrosion of tantalum in wet chlorine at temperatures above 350 °C (660 °F), but the amount of water was not specified (Ref 46).

Nonmetals are frequently used in wet chlorine gas because of its corrosivity to most metals, particularly to carbon steel equipment that is widely used in the dry gas. Caution is warranted because, as with many metals, many nonmetals work in either wet or dry chlorine but not both.

The materials used in equipment for the production of chlorine are reviewed in Ref 48.

Glass-lined steel, fiber-reinforced plastic, PTFE equipment, PVDF equipment, and selected elastomers are resistant to moist chlorine under the same conditions as described previously for dry chlorine. The same caveats apply regarding permeation, following manufacturers' recommendations, and properly accounting for secondary stresses on monolithic nonmetallic equipment.

Polypropylene, polyethylene, and graphite also have the same limitations in moist chlorine as described for dry chlorine.

Chlorine-Water

Chlorine dissolved in water forms a mixture of HCl and hypochlorous acid (HClO). See the article "Corrosion by Hydrogen Chloride and Hydrochloric Acid" in this Volume. Hypochlorous acid is very oxidizing, which makes the mixture extremely corrosive. Relatively little information is available on corrosion in water containing substantial levels of chlorine, especially near saturation. Aluminum was reported to be unsuitable in HClO and to be attacked with extensive pitting in chlorine-water environments (Ref 17). Zirconium was found to corrode at less than 0.025 mm/yr (1 mil/yr) in chlorine-saturated water (Ref 26).

Corrosion of several alloys in chlorine-saturated water at 25 °C (75 °F) was investigated (Ref 43), and the results, presented in Table 4, show that rates are generally low for the chromium-containing alloys tested and for titanium. Only Monel 400 showed a very high rate (24 mm/yr, or 948 mils/yr), which is to be expected because of its sensitivity to oxidants. No large difference in performance between cast alloys and their wrought equivalents was found, except for crevice attack on ACI CF-8M, CN-7M, and CD-4MCu.

Related tests were performed in chlorine ice at −20 °C (−4 °F) (Ref 43). The results, given in Table 5, show that corrosion rates for chromium-containing alloys are below 0.0025 mm/yr

(0.1 mil/yr), except for ACI CW-12M at 0.0038 mm/yr (0.15 mil/yr). Higher, but not unacceptable, rates were found for steel, N-12M, and M-35. These alloys are sensitive to oxidants in acidic environments, which explains their poorer performance.

Corrosion by Alkalis

Michael Davies, CARIAD Consultants

TRUE ALKALINE CHEMICALS include caustic soda, or sodium hydroxide (NaOH), caustic potash, or potassium hydroxide (KOH), and soda ash, or sodium carbonate (Na_2CO_3). They are reviewed in this article and provide a basis for general discussion of various alkaline exposures.

Caustic Soda—Sodium Hydroxide

Caustic soda is one of the three most prominent products of the chemical industry, the other two being sulfuric acid and soda ash. By the 1990s, more than 13 million tons were used annually in the United States alone. Major West European caustic soda capacity in 2003 was estimated to be 11.3 million tons/yr (Ref 1). The annual worldwide production of caustic soda is of the order of 45 million tons (Ref 2). As of July 2002, more than 500 companies produced chlor-alkali (a general term to cover the coproduction of chlorine and caustic soda) at more than 650 sites worldwide, with a total annual capacity of more than 51 million metric tons of chlorine. About half of all plants are located in Asia, but many of these are relatively small (Ref 3).

Caustic soda is the most important commercial caustic chemical and is used in a variety of processes, for example, plastics (notably polyvinyl chloride, PVC), pulp and paper, soap, glass, aluminum, and so forth. It is also used for acid waste neutralization, although soda ash is equally effective and less expensive. In waste-management programs, caustic soda is observed to be about 100 times more soluble than lime, a less expensive substitute for such applications.

There are a number of processes that can be used to make caustic soda, but the majority is produced as a by-product of the electrolysis of brine to produce chlorine. The three major electrolysis processes used in the manufacture of chlorine and caustic soda are:

- Diaphragm cell
- Mercury cell
- Membrane cell

These three processes produce caustic soda of differing strengths and purities, and most of the

diaphragm and membrane cell caustic must be further purified and then concentrated by evaporation.

Caustic potash or potassium hydroxide is an analogous chemical, sometimes used as a substitute in papermaking processes, but it is more expensive and of lesser commercial importance. The term “caustic” is often used to describe both caustic soda and caustic potash.

Aluminum and Aluminum Alloys

Aluminum is rapidly attacked by even dilute solutions of caustic soda at all temperatures. The aluminum ion (Al^{3+}) is readily complexed by hydroxyl ions (OH^-). Dilute solutions ($<1\text{ N}$) can be inhibited by saturating with potassium dichromate. Aluminum should not normally be considered for service above about pH 8.5 (Ref 4). The corrosion of aluminum in caustic is controlled by the competing processes of film growth and dissolution. The film formed consists of an inner compact layer and an outer crystalline one. At pH around 9 or less corrosion rate is low, but at higher pH cavities form in the outer layer permitting access of the fluid to the surface and increasing corrosion rate. At pH 12 these cavities are more prominent and severe localized corrosion occurs. The corrosive effect of increasing solution pH for aluminum at different temperatures is clearly seen in Fig. 1 (Ref 5). The addition of 1000 ppm chloride ions decreased the corrosion rate at 60 °C (140 °F), but had no appreciable effect at 30 °C (85 °F).

Impurities present in NaOH can have a strong effect on the corrosion of aluminum. Impurities such as Fe^{2+} can be reduced on the metal surface forming preferential sites for hydrogen evolution and greatly increasing corrosion current. Aluminates in solution contribute to a slight decrease in corrosion current (Ref 6).

Iron and Steel

Ferrous alloys are very commonly used in caustic soda service, provided iron contamination is not objectionable and provided certain restrictions are imposed on service conditions to avoid stress-corrosion cracking (SCC). At ambient temperatures, iron and steel are

protected by a passive layer of magnetite. Magnetite is the least soluble iron oxide in alkaline solutions, so corrosion is largely prevented under these conditions (Ref 7). At elevated temperature, magnetite has been found to be either protective or nonprotective depending on the growth conditions. A protective film grows at the metal/oxide interface with “excess” iron ions forming soluble ferroates while the nonprotective magnetite film becomes highly stressed as it grows at the oxide/solution interface. The breakdown of the protective film also occurs at more elevated temperatures and under turbulent or erosive conditions (Ref 8).

Cast Irons. Gray cast iron is resistant to caustic but is usually not used because of safety

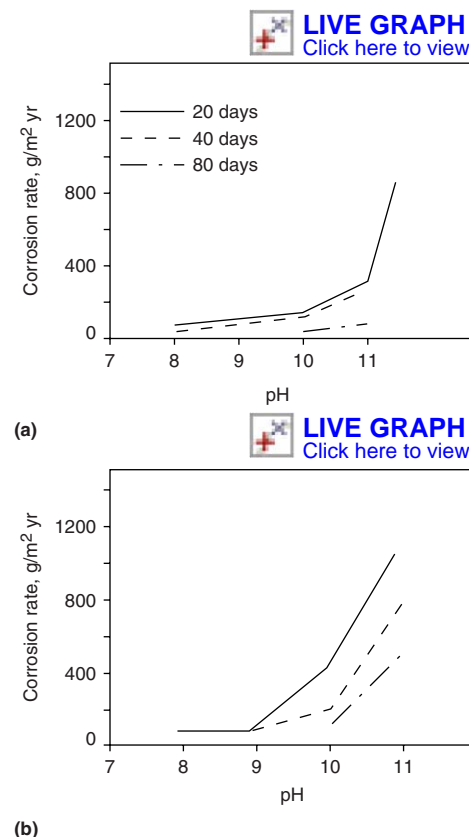

Fig. 1 Effect of pH on the corrosion rate of aluminum in NaOH at 30 °C (85 °F) (a) and 60 °C (140 °F) (b). Source: Ref 5

problems associated with its brittle nature. At one time, caustic soda solutions were concentrated in cast iron evaporators.

Hot alkalis at >30% concentration attack unalloyed irons. Temperature should be <80 °C (<175 °F) in concentrations up to 70% if the corrosion rate is not to exceed 0.25 mm/yr (10 mils/yr). The corrosion rate of ductile cast iron is similar to that of gray cast iron, but ductile iron can be susceptible to cracking in highly alkaline solutions while gray cast iron is not (Ref 9). Ductile cast iron is, however, sometimes used for specific items, such as valves or pumps.

The addition of nickel greatly reduces the corrosion rate of cast iron in boiling 50 to 65% caustic, as shown in Table 1 (Ref 10). This was an 81 day test under vacuum of 660 mm (26 in.) mercury.

The austenitic nickel cast irons of greater than about 15% Ni content, for example, NiResist (International Nickel Co.) types 1 (F41000), 2 (F41002) and the ductile NiResist type D2 (F43000) are much more resistant than unalloyed cast iron in caustic solutions up to about 70%. Corrosion rate should be <0.25 mm/yr (<10 mils/yr) in solutions up to 70% NaOH at temperatures approaching boiling (Ref 9). The resistance is roughly proportional to the nickel content unless sulfur or sulfur compounds are present. The nickel-containing cast irons may be susceptible to SCC, especially in the presence of high chlorides, so it is considered a reasonable precaution to stress relieve these alloys before use in hot caustic soda solutions. Detailed corrosion data for NiResist is compared with that of unalloyed cast iron in Table 2 (Ref 11).

The resistance of unalloyed and alloyed cast irons in molten caustic soda is shown in Table 3 (Ref 12). These data show that nickel has superior resistance to all these cast irons, including the highly alloyed ones.

High-silicon cast irons have good resistance to relatively dilute caustic soda solutions at moderate temperatures. This type of iron, for example, the 14.5% Si cast iron (F47003) is not resistant at higher strengths of caustic at elevated temperature because NaOH reacts with the siliceous film from which it derives its acid

resistance. High-chromium cast irons are also not resistant to strong alkaline solutions.

Carbon and Low-Alloy Steels. Some early data on the corrosion of steel in ambient temperature is shown in Table 4. These data show that corrosion rate decreases with increase of caustic concentration at room temperature (Ref 13). At ambient temperature, steels are only slightly attacked by caustic soda with solution strength having little effect on rate. Unalloyed and low-alloy steel corrode at <0.005 mm/yr (<0.2 mil/yr) in up to 20% NaOH at ambient temperature. In stronger solutions, 20 to 50%, the corrosion rate will be <0.01 mm/yr (<0.4 mil/yr), and the steel is still usually protected by the presence of a passive layer of magnetite (Ref 7). At higher strengths and temperatures, this oxide layer no longer provides effective protection and corrosion rates increase.

The stated limits for the use of carbon and low-alloy steels in caustic soda solution at temperatures above ambient vary widely. Typical suggested limits on the basis of metal loss by corrosion are 50% concentration at temperature up to 85 to 90 °C (185 to 195 °F) (Ref 14) and 50% at up to 60 °C (140 °F) (Ref 15). One source says that the corrosion rate in 50% will be <0.025 mm/yr (<1 mil/yr) at 40 °C (105 °F), 0.13 mm/yr (5 mils/yr) at 60 °C (140 °F), and

0.2 mm/yr (8 mils/yr) at 55 to 75 °C (130 to 165 °F) (Ref 16), while another source says that the corrosion rate in 50% will be 0.06 mm/yr (2.5 mils/yr) or less at 21 to 38 °C (70 to 100 °F) (Ref 15). Some of the discrepancy between various stated safe limits is caused by other factors such as purity of the caustic soda, velocity, oxygen, concentration effects leading to caustic SCC, and so forth. In other strengths of caustic there is less discrepancy, and typically carbon steel is said to be satisfactory up to 70% at up to 80 °C (175 °F) (Ref 17) and in 75% at up to 100 °C (212 °F), assuming iron contamination is acceptable (Ref 18).

These limits of operating conditions are based on reasonable rates of metal loss and assume that iron contamination of the solution is acceptable. If this is not the case, then a more resistant material must be employed or the vessel must be lined. Storage tanks are often lined with neoprene, phenolic-epoxy, or other resistant coating or lining. In the absence of concerns about iron contamination, bare steel tanks are used effectively to store caustic solutions up to about 50% concentration and up to about 65 °C (150 °F) (Ref 9).

If steel is under tensile stress, as from welding or cold work (e.g., field-flaring of pipe flanges) and is exposed to caustic soda, caustic SCC is

possible. Under these conditions a safe operating limit might be up to 50% caustic at up to 65 °C (150 °F), although cracking has occurred at temperatures as low as 48 °C (118 °F) (Ref 19). A survey of field experience was used to produce a curve that indicated temperatures and caustic strengths above which cracking was possible. These data were thought to be conservative but were based on many years of practical experience (Ref 20). Another curve depicting the parameters of caustic concentration and service temperature above which caustic cracking may be a problem was produced from short-term (up to 62 days) laboratory tests (Fig. 2) (Ref 21). This curve is also thought to be conservative but is widely used and reproduced in various forms. Failures that occasionally occur in the safe zone are likely to be associated with other factors such as localized overheating or contaminants present in the caustic.

Figure 3 shows the suggested regions, as defined by temperature and concentration, in which postfabrication thermal stress relief (or an alternative alloy) is recommended to avoid SCC in steels (Ref 22).

An iron alloy with 3% Ni was found to be immune to caustic cracking, and the addition of 0.5% Mo had little effect on that SCC resistance. However, segregation of phosphorus at grain boundaries significantly reduced resistance. Similarly, the presence of carbon or carbides increases the risk of this type of intergranular

Fig. 2 Temperature and concentration of caustic soda that can cause SCC of carbon steels. Source: Ref 21

SCC. These conclusions are probably applicable to other low-alloy steels (Ref 23).

Stainless Steels

All of the standard stainless steels are resistant to general corrosion by all concentrations of caustic soda up to about 65 °C (150 °F). If low levels of iron are required in the product then more resistant alloys or coatings may be needed. The resistance to general corrosion in caustic is almost directly proportional to nickel content. Stainless steels, however, are subject to SCC at certain concentrations and temperatures.

Ferritic Grades. The standard ferritic grades of stainless steel such as types 409 through 430 (S40900 to S43000) and 434 and 444 (S43400 and S44400) contain 11 to 17% Cr with carbon and nitrogen levels kept low to avoid embrittlement. These standard ferritic grades are not generally as resistant in caustic as the standard austenitic stainless steels. For example, in 60% NaOH at 100 °C (212 °F) type 444 corroded at 0.61 mm/yr (24 mils/yr) while type 304 austenitic had a corrosion rate of

Fig. 3 Temperature and concentrations of caustic soda that require stress relief to prevent SCC of carbon steel. Source: Ref 22

0.07 mm/yr (3.0 mils/yr) (Ref 24). Some of the standard ferritic grades are compared with the standard austenitic stainless steels in Table 5 (Ref 12).

There are now much more highly alloyed and corrosion-resistant ferritic stainless steels, commonly known as superferritics. The first of these superferritic stainless steels was based on 26% Cr, 1% Mo (S44627), and the niobium-stabilized XM-27 (S44627). These were developed to provide better resistance to chloride SCC than the austenitic 300 series. These ferritic steels have low interstitial content with high chromium and very low carbon levels. Other superferritic stainless steels are based on a 29% Cr, 4% Mo alloy, and they need low C + N levels, that is, less than 0.025%, to avoid intergranular corrosion caused by chromium depletion from precipitation of carbides and nitrides. Some of the current ferritics contain higher levels of C + N and have additions of titanium or niobium as carbon/nitrogen stabilizers. Superferritic steels include AL 29-4C (Allegheny Ludlum) (S44735), AL 29-4-2 (Allegheny Ludlum) (S44800), Sea-Cure (Crucible, Inc.) (S44660), E-Brite (Allegheny Ludlum) (S44627), and Monit (Uddeholm, now Outokumpu Stainless) (S44635).

While standard austenitic stainless steels show high rates in boiling 50% caustic, the higher alloy 20 and the superferritic grades tend to be resistant, as shown in Table 6 (Ref 25) and Table 7 (Ref 26–29). The corrosion rates in all

cases are unacceptably high, except for alloy 20 (N08020) and the superferritic stainless steels. In the standard 300 series stainless steels the weld is less resistant than the base metal and the low-carbon L grade more resistant than the normal carbon grades.

A high-purity 30% Cr, 2% Mo (Shomac 30-2) alloy was studied in hot, concentrated caustic and was found to be resistant to caustic strengths up to 50% at temperatures below 120 °C (250 °F) under isothermal conditions. In more concentrated solutions at higher temperatures most specimens suffered from intergranular attack (IGA). Under heat-transfer conditions, corrosion was more severe and IGA was seen even at lower caustic concentrations. The cause of IGA was found to be carbide or nitride precipitation at grain boundaries leading to localized chromium depletion. This mechanism was analogous to that occurring in austenitic stainless steels so the same test methods for susceptibility can be applied. Galvanic coupling to more active metals prevented IGA, but potential must be strictly controlled to avoid active dissolution (Ref 30).

Ferritic alloys E-Brite (S44627), 2¼Cr-1Mo (K21950), type 446 (S44600), and 26-1S (S44626) were included in tests to determine corrosion and caustic SCC in high-temperature NaOH solutions (Ref 31). It was found that in deaerated 50% NaOH at temperatures in the range 284 to 332 °C (543 to 630 °F) these ferritic alloys were severely corroded and their susceptibility to caustic SCC was dependent on their heat treatment.

Superferritic alloys are sometimes used for heat-exchanger tubing. They have also been successfully used in caustic evaporators, but require a sustained supply of oxidizing contaminants, such as chlorates, to maintain passivity at these higher concentrations and temperatures. The high-purity 26-1 grade (S44626) containing niobium and molybdenum is useful up to about 175 °C (350 °F) in caustic evaporators, depending on the caustic, chloride, and other contaminant concentration (Ref 9). This type of ferritic stainless steel has been generally successful in evaporators, but failures have occurred from either localized or general corrosion. These failures have been associated with one or more of the following factors (Ref 14):

- Increase in carbon levels in the alloy due to pickup from oil, grease, or other hydrocarbon contamination during tube preparation
- Temperature in the first-effect evaporator >150 °C (>300 °F)
- High local tube temperatures caused by blockages with insoluble salts

It has been shown that environmentally assisted cracking (EAC) in caustic is related to hydrogen formation so that conditions that encourage hydrogen permeation also encourage caustic cracking. Type 410 martensitic steel was found to be immune to cracking in concentrated, deaerated caustic soda solution up to 90 °C (195 °F) (Ref 32).

The precipitation-hardening (PH) stainless steels see limited service in caustic environments. These alloys exhibit very high strengths combined with good notch toughness and corrosion resistance. For this reason, they are often the preferred material for such parts as valve stems and certain critical fasteners. Some of these alloys are susceptible to hydrogen embrittlement in corrosive or hydrogen-rich environments.

Corrosion rates are acceptable in concentrated caustic at moderate temperatures, as shown in Table 8 (Ref 33). At boiling point in 50% caustic this martensitic alloy 17-4PH (S17400) in condition H1075 was severely corroded. Tests were carried out for five 48 h periods.

Duplex stainless steels are not commonly used in caustic soda applications except where their resistance to chloride SCC is useful from the water side of heat exchangers. The modern grades, for example, alloy 2205 (S31803), typically also contain molybdenum to achieve a composition of about 22% Cr, 5.5% Ni, 3% Mo, and 0.03% C max, strengthened and stabilized by nitrogen additions. The mixed austenite-ferrite structure imparts strength and resistance (but not immunity) to chloride pitting and SCC. They have a higher strength than the lower austenitic grades such as type 304 (S30400) but are subject to temper embrittlement at about 475 °C (885 °F).

Corrosion testing in a range of caustic solutions at boiling point showed that duplex alloys can be used in boiling solutions up to at least 30% with negligible corrosion (Fig. 4) (Ref 34). The tests also showed that these duplex alloys were not susceptible to SCC in boiling caustic solutions from 20 to 70%.

Corrosion rates of duplex stainless steels Uranus 50 (Creusot-Loire) (21Cr, 6.6Ni, 2.3Mo) and Ferralium 255 (Langley Alloys) (26Cr, 5.6Ni, and 3.2Mo) in boiling caustic soda up to 30 mass% was less than 0.01 mm/yr (0.39 mil/yr) with uniform corrosion rates. The rate increased with caustic concentration, reaching a maximum at 60%, and in these more concentrated solutions the austenitic phase was slightly more attacked than the ferritic phase. Small flow rates (e.g., 0.08 m/s, or 2.6 ft/s, rotating disc) increased the corrosion rate by a factor of six compared with stagnant conditions. Further increases in flow rate up to 1 m/s (3.3 ft/s) had no further effect on corrosion rate (Ref 35). E-Brite and 7-Mo (Carpenter

Technology) stainless steels showed good resistance to SCC and corrosion in 50% caustic at 135 °C (275 °F) (Ref 9).

Welding tends to lead to variations (20 to 80%) in the austenite/ferrite ratio in the as-cast weld bead and fusion zone. To minimize this effect, they are welded with a nickel-rich, over-matching rod whose higher nickel content is beneficial in caustic service.

Recent corrosion testing of various duplex stainless steels in 30 to 70% NaOH solutions found that their resistance was on the order of:

$$2304 < 2205 < 2507 < S32906 \text{ (Safurex)} \\ < \text{alloy X (a proprietary duplex alloy)}$$

Alloy 200 (N02200) had a lower corrosion rate than any of the duplex alloys in pure caustic solutions at any test temperature. Statistical analysis of the results showed that the most important alloying elements to produce resistance to caustic corrosion in the duplex alloys were chromium, nitrogen, and nickel. The effect of chromium in the austenite phase was investigated in a set of experimental duplex alloys. It was found that corrosion resistance was directly proportional to the chromium content. The range of chromium contents was from 26.54 to 29.04% with corrosion rates in boiling 60% NaOH of 0.39 to 0.05 mm/yr (15.4 to 1.97 mils/yr), respectively. Stress-corrosion cracking tests in 50% NaOH at 137 °C (279 °F) showed that S32906 was immune to cracking in this environment (Ref 36).

Because of the uncertainties about the amount of chlorides and oxidizing salts such as hypochlorites and chlorates, extensive field corrosion tests should be made before selecting duplex stainless steels for caustic soda service.

Austenitic Grades. There is little difference in the corrosion resistance of type 304L (S30403) and 316L (S31603) in 50 or 73% caustic solutions. No difference was found between the corrosivity of diaphragm cell caustic and mercury cell caustic in an extensive survey of caustic soda producers (Ref 37).

Source: Ref 33

Fig. 4 Corrosion resistance of duplex stainless steels in boiling NaOH solutions. Source: Ref 34

Corrosion of 18-8 steels in hot, concentrated caustic solutions was found to increase under heat-transfer conditions, possibly due to localized evaporation and erosion of the passive film by gas bubbles. The molybdenum-containing type 316 (S31600) was found to be less resistant than type 304 (S30400). Annealed and sensitized specimens were subject to IGA when held in the passive region. When in the active region, attack was general and transgranular (Ref 38).

All austenitic stainless steels resist general corrosion by all concentrations of caustic soda up to about 65 °C (150 °F). Other authorities give higher temperature limits for 50% caustic, but these are probably influenced by other factors such as presence of impurities in the caustic. Type 304 and 316 show low corrosion rates in boiling caustic at concentration up to nearly 20%. Type 316 has a better resistance to pitting than type 304 in caustic solutions, especially if chlorides are present. The low-carbon grades perform marginally better than the high-carbon grades because of their resistance to sensitization. This means that type 316L is a good choice for caustic solutions as long as operating conditions are such that caustic SCC is not a problem (Ref 9). Stress-corrosion cracking of 304 and 316 grades occurs at around 100 °C (212 °F). An isocorrosion curve in mm/yr for these grades is shown in Fig. 5 (Ref 39). This figure also shows the temperature and concentration region where caustic SCC of these steels is likely.

The resistance to caustic SCC in 30% NaOH at 200 °C (390 °F) increased in the order: N08904 (least resistant) < S31603-F138 < S31803 (most resistant). (F138 is a special grade of S31603 with lower levels of inclusions.) In this environment the addition of sulfide (20 g/L Na₂S·9H₂O) dramatically increased the susceptibility of all these alloys to SCC (Ref 40). Slow-strain-rate tests in the same environment determined that the order of resistance for the alloys tested was:

$$904L > 825 > \text{alloy 28} > \text{alloy 33}$$

Resistance increased as the chromium content of the alloy increased. When sulfide ions were added, alloy 33 (R20033) showed excellent corrosion resistance to pure caustic soda but was very prone to SCC even at very low strain rates (Ref 41). The zone of concentration and temperatures in which SCC is possible for 904L (N80904) is shown in Fig. 6 (Ref 42). This figure also shows the isocorrosion curve at 0.1 mm/yr (4 mils/yr) corrosion rate for this and other stainless steels and for titanium.

Caustic cracking can also be caused by potassium hydroxide. A type 304L (S30403) bypass line in a steam methane reforming unit failed by SCC in KOH that was formed from a potassium-promoted catalyst. Cracking at relatively low temperatures was possible only in the presence of hydrogen and/or carbon monoxide. This study found that NaOH caused cracking at lower temperatures than did KOH (Ref 43).

Cast stainless steels perform well in caustic soda, and they are frequently used in pumps and valves. While corrosion rates are similar to those of their wrought equivalents, the nature of the cast surface means that caustic SCC is not a problem. Cast stainless steels are often used at operating conditions well in excess of those of the wrought version (Ref 9).

The equivalent cast version of types 304 (S30400) and 304L (S30403) are CF-8 (J92600) and CF-3 (J92500), respectively, and they exhibit approximately the same corrosion response as the wrought alloys (Ref 44).

Castings can, however, have surface layers containing more than the maximum allowable carbon content of 0.08%, which can significantly reduce corrosion resistance of the surface. In the cast form, the difference between CF-8 (J92600) or CF-3 (J92500) and the corresponding molybdenum-bearing grades CF-8M (J92900) and CF-3M (J92800) is insignificant. CF-3 or CF-8 are not particularly common, and manufacturers of cast pumps and valves tend to standardize on CF-8M, which has a broader range of applications. The molybdenum-grade castings are often more available and less expensive than the 304 or 304L grade equivalents. Since the cast version of these alloys is unlikely to be welded, there is rarely a justification for specifying the low-carbon grades in this case. This assumes that the valves or pumps, if weld repaired by the manufacturer, are properly reheat-treated (solution annealed) to restore optimum corrosion resistance. Availability and price are likely to favor the non L grade, and a properly heat treated casting in CF-8 or CF-8M is likely to be as corrosion resistant as its low-carbon cast or wrought equivalent.

High-Performance Austenitic Alloys

There is a group of high-performance austenitic alloys, sometimes called corrosion-resistant

Fig. 5 Isocorrosion curves for type 304 and 316 stainless steels in caustic soda also showing limits of SCC. Source: Ref 39

alloys (CRAs) or superaustenitic alloys, which consist of both stainless steels (i.e., containing >50% Fe) with high chromium and nickel content and alloys with nickel as the predominant alloying element. The latter group are not true nickel-base alloys because they contain <50% Ni. The original high-performance austenitic alloys were the molybdenum-free alloy 800 (20Cr, 30Ni; N08800) and the molybdenum-containing alloy 20Cb3 (Carpenter Technology) (20Cr, 33Ni, 2.5Mo; N08020). Molybdenum is now a common alloying element in this group of superaustenitic alloys that started with the stainless steel 254SMO (20Cr, 18Ni, 6Mo; S31254). The molybdenum in this type of alloy gives resistance to chloride pitting, crevice corrosion, and chloride SCC.

Alloy 800 (N08800) has been used in up to 73% caustic at 120 °C (250 °F), but is susceptible to caustic SCC above 150 °C (300 °F). Alloy 825 (N08825), which has 3% Mo, is slightly more resistant than alloy 800 (N08800). These nickel-chromium-iron alloys with and without molybdenum (e.g., N08800, N08825, N08020) have useful resistance up to 73% caustic at temperatures up to about 120 °C (250 °F). The beneficial effects of nickel and molybdenum in nickel-containing and nickel-base alloys is shown in Fig. 7 (Ref 45). These data show that both these alloying elements improve corrosion resistance in this caustic solution. The effect of molybdenum is minimal above about 3 to 4% Mo.

In studies of austenitic and duplex alloys in 30 wt% NaOH at 150 °C (300 °F), it was found that under deaerated conditions chromium and nickel passivate the alloys and iron is dissolved. Under very oxidizing conditions chromium was dissolved, probably as hexavalent chromium (Cr^{VI}), and nickel and iron form a thicker, less protective oxide film. Caustic SCC cracking occurred only in alloy 800 (N08800) at high anodic potentials where chromium is being dissolved from the oxide (Ref 46).

In oxygenated 50% caustic at 300 °C (570 °F) an increase in nickel content between 15 and

Fig. 6 Isocorrosion curve for a corrosion rate of 0.1 mm/yr (0.4 mil/yr) for 904L (N80904), other stainless steels, and titanium. BP, boiling point; SCC, stress-corrosion cracking. Source: Ref 42

45% was found to improve the caustic SCC resistance of Fe-Ni-Cr alloys containing 10 to 15% Cr, but had little effect on alloys with 20 to 25% Cr (Ref 47). Nickel also has a beneficial effect on the corrosion resistance of iron-base alloys in hot caustic solutions. The higher the nickel content, the lower is the corrosion rate as shown in Fig. 8 (Ref 48). The maximum benefit is reached at about 20% Ni with little further benefit from further increases in nickel into the nickel-base alloys. These data also show that when the caustic was deaerated (with hydrogen) the corrosion rates for all of these metals and alloys were reduced.

Comparative tests of various stainless steels in 50% NaOH are shown in Table 9 (Ref 49). This

table shows the lowest temperature at which the corrosion rate exceeds 0.127 mm/yr (5 mils/yr). These same data are plotted for the three alloying elements in Fig. 9. Nickel has a strong beneficial effect on corrosion resistance while there is no apparent benefit of additional molybdenum or chromium in this environment, within the range of compositions represented by these steels.

Data on the corrosion of the 6% Mo austenitic stainless steel, AL-6XN (N08367), and other steels and alloys in boiling 50% NaOH are shown in Table 10 (Ref 50). These data show that none of these materials is really acceptable for this use.

For pumps and valves, a cast version of the “20” type alloy CN 7M (20Cr, 29Ni, 3Mo;

N08007) is quite often employed (Ref 51, 52). Corrosion rates are below 0.13 mm/yr (5 mils/yr) for the complete range of NaOH concentration at temperatures up to the atmospheric boiling point.

Alloy 28 (N08028) is another Fe-Ni-Cr alloy that has useful resistance to caustic solutions, particularly if contaminated. This alloy is compared with alloy 800 (N08800) and 904L (N08904) in NaOH with and without chlorides in Table 11 (Ref 53). Tests were carried out for an initial 1 day period, followed by two other test periods of 3 days each. These data show that the presence of chlorides do not significantly increase corrosion in these alloys; in fact, they decrease the corrosion of alloy 28 and alloy 800 in the 43% caustic.

The effect of nickel on the corrosion resistance of Fe-Cr-Ni alloys is shown in Fig. 10 (Ref 54). The results of tests in 28% NaOH with 8% NaCl at 99 °C (210 °F) show that nickel-free and high-nickel alloys are resistant with a maximum corrosion rate at about 5% Ni. The solid data points in this figure relate to alloy 28 (N08028) that has good resistance in this chloride-contaminated environment. This alloy has been used for the evaporation of diaphragm cell NaOH. In this application erosion by sodium chloride crystals can be a problem, and this alloy showed considerably better performance than pure nickel.

Alloy 33 (stellite) (R20033) is an austenitic alloy based on chromium with a nominal analysis of 33% Cr, 32% Fe, 31% Ni, 1.6% Mo, 0.6% Cu, and 0.4% N. Testing in caustic soda has shown that it could be used to replace standard austenitic stainless steels in, for example, pipes or vessels for hot caustic solution where type 316Ti is limited to 90 °C (190 °F). Alloy 33 could be acceptable in 25 and 50% NaOH up to boiling point based on 28 day laboratory tests (Table 12) (Ref 55).

Krupp VDM alloys were exposed in caustic evaporators in various Russian plants and subject to laboratory evaluation. This study concluded that (Ref 56):

- Alloy 201 and its welded joints were resistant to corrosion in evaporation of electrolytic caustic soda solutions (from both mercury and diaphragm cells) up to 60% NaOH at temperatures up to 170 °C (340 °F); increased grain growth (index 2 to 3) was seen in the heat-affected zone (HAZ) of the welded joints

of alloy 201, which may be a contributing factor to the failure of the welded joint of the alloy 201 in diaphragm caustic soda in more severe conditions (65 to 70% NaOH, 180 to 195 °C, or 355 to 385 °F). Intergranular and knifeline (IGA) corrosion was seen in the welded joint, and the weld metal suffered selective corrosion. The overall corrosion rate of the welded joint of alloy 201 was 0.8 mm/yr (31.5 mils/yr).

- The base metal and welded joints of alloy 201 were fairly corrosion resistant when concentrating to more than 60% NaOH of mercury cell caustic soda; alloy 33 and its welded joints possess good resistance under the conditions of evaporation concentration of diaphragm cell caustic soda (up to 65% NaOH), but, as the concentration increased to 70%, the corrosion rate of the welded joint increased to 0.3 mm/yr (11.8 mils/yr) with general corrosion and marked etching of the weld metal; at higher concentrations of the diaphragm cell caustic soda the alloy suffered pitting corrosion.
- Alloy 33 was resistant in concentration from 45 to 60% of mercury cell caustic soda (free from chlorides), but not as resistant as alloy 201 (0.019 and 0.0065 mm/yr, or 0.75 and 0.26 mil/yr, respectively). At caustic soda concentrations that increased from 60 to 97.5%, the corrosion rate of alloy 201 was about three times that of alloy 33 (0.336

and 0.125 mm/yr, or 13.2 and 4.9 mils/yr, respectively). Upon further concentration of the caustic soda to 99.5%, the corrosion rate of alloy 201 was about 20 times higher than that of alloy 33 (0.0485 and 0.0022 mm/yr, or 1.9 and 0.09 mils/yr, respectively).

At temperatures of the order of 300 °C (575 °F), 25% caustic will cause SCC of the CRAs. It is very important when both chlorides and caustic are present in an environment known to cause SCC to know which is the active species. If it is the chloride, a CRA will suffice to overcome the problem; whereas, if caustic is the cause of the cracking then a high-nickel alloy will be needed.

Nickel and Nickel Alloys

The nickel-base alloys are generally preferred for caustic soda service, but are not without their problems. They may be discussed under separate groupings that distinguish between the chromium-free alloys (resistant to reducing corrosive conditions) and the chromium-bearing alloys, which are more resistant under oxidizing conditions. While nickel and nickel alloys can suffer from caustic SCC in very hot, concentrated caustic, alloy 600 is more resistant than unalloyed nickel (Ref 57). Alloy 400, alloy 600, and alloy 690 are all susceptible to SCC over a wide range of caustic concentrations at temperatures above 290 °C (550 °F) (Ref 58).

Chromium-Free Alloys. Commercially pure nickel, alloy 200 (N02200), is one of the best metals for resisting corrosion while simultaneously avoiding unacceptable metal contamination. Alloy 200 has a corrosion rate of <0.005 mm/yr (<0.2 mil/yr) below 50% NaOH at up to boiling temperature. Above 315 °C (600 °F), the low-carbon variant, alloy 201 (N02201), must be used to avoid embrittlement by graphitization and attendant intergranular attack (Ref 59). The mechanical strength of nickel also diminishes at elevated temperatures, encouraging the use of chromium-bearing nickel alloys.

Nickel has corrosion rates of <0.0025 mm/yr (<0.1 mil/yr) up to 73% NaOH at 115 °C (240 °F) and only 0.025 mm/yr (1 mil/yr) at 130 °C (265 °F). Caustic soda is usually

produced at 11 to 15% solution and concentrated up to 50% or higher by evaporation in alloy 200 vessels. It has outstanding corrosion resistance to caustic soda at all concentrations up to anhydrous at boiling or molten temperatures (Ref 9).

Nickel is more severely attacked in hot, concentrated caustic under heat-transfer conditions and in the presence of chlorates in solution (Ref 60). The presence of oxidizable sulfur compounds also increases the corrosion of nickel in caustic. The effect is more pronounced with sulfides such as hydrogen sulfide, mercaptans, or sodium sulfide and, to a lesser extent, with partly oxidized compounds such as thiosulfates and sulfites (Ref 59).

When nickel ion contamination must be minimized, cathodic protection may be applied in concentrators and storage tanks, with effective current densities as low as 0.11 A/m² (0.01 A/ft²) (Ref 16). The corrosion rate increases linearly with increasing concentration of chlorate and other oxidizing contaminants.

The behavior of alloy 201 (N02201) is compared with other nickel alloys in molten caustic in Table 13 (Ref 61). It can be seen that nickel is more resistant to corrosion in molten caustic than the more highly alloyed materials even at elevated temperature.

In molten caustic containing 0.5% sodium chloride, 0.5% sodium carbonate, and 0.03% sodium sulfate at 510 °C (950 °F), the corrosion rate of wrought nickel was 0.23 mm/yr (9 mils/yr). This high rate was still much lower than rates measured for other alloys tested (Ref 12). Rates of over 1.27 mm/yr (50 mils/yr) were measured for nickel in laboratory tests in 75% caustic concentrated to the anhydrous product at 480 °C (900 °F). This rate was also much lower than the other alloys tested apart from silver, which corroded at a rate of 0.135 mm/yr (5.3 mils/yr) (Ref 62). In plant exposures at up to 540 °C (1000 °F) in 73% caustic soda, the corrosion rate of nickel was 6.60 mm/yr (260 mils/yr). This unexpectedly high corrosion rate was probably due to sulfur and nitrate contamination (Ref 63).

The least expensive chromium-free, nickel-base alloy is alloy 400 (N04400), which is stronger than nickel itself. It is used in caustic soda service up to about 73% but, having a

Source: Ref 55

copper content of around 25 to 35% may be objectionable from the contamination standpoint in some applications where it might be suitable from the corrosion viewpoint. It is less resistant than nickel at concentrations above 73% at the atmospheric boiling point and can suffer SCC in hot caustic. It is subject to SCC at higher temperatures, for example, in 2 to 2.7 MPa (300 to 400 psi) steam contaminated with alkaline boiler-treating chemicals. Also, liquid metal embrittlement (LME) has occurred with alloy 400 (N04400) components handling mercury cell caustic.

Alloy K-500 (N05500), a tougher and more abrasion-resistant variant that undergoes precipitation hardening, has substantially the same corrosion characteristics as alloy 400.

Results of plant tests of various nickel-base alloys and other materials in caustic evaporators are shown in Table 14 (Ref 59). These data show the superiority of nickel over the other alloys, but also show that alloy 400 and alloy 600 have acceptable corrosion resistance.

Nickel-clad steel plate is often used to simultaneously provide the corrosion resistance of nickel and the strength of steel at moderately elevated temperatures. Of course, to prevent corrosion of the substrate and iron contamination, special precautions must be taken in fabricating and welding.

The molybdenum-rich alloy B2 (N10665) has good corrosion resistance in the absence of oxidizing contaminants, but finds no application

because of the excellent resistance of nickel itself.

Although electroless nickel plating (ENP) has a corrosion resistance superior to pure nickel 200 (N02200), such coatings are used only to minimize iron contamination since they contain "holidays" that allow the caustic solution to access the steel surface. The resistance of ENP in caustic depends on its phosphorus content. The phosphorus is present since ENP is produced by the autocatalytic reduction of nickel in the presence of sodium hypophosphite. In tests of ENP samples with various phosphorus contents (from 0 to 18.2 at.%) in 50% NaOH at room temperature it was found that (Ref 64):

- All coatings had corrosion rates of ≤ 0.002 mm/yr (≤ 0.08 mils/yr).
- High-phosphorus electroless nickel (HPEN) was less resistant than low phosphorus (LPEN) or medium-phosphorus electroless nickel (MPEN) coatings in hot, concentrated NaOH. The LPEN and MPEN coatings had corrosion rates similar to pure nickel in this environment.
- This inverse effect of phosphorus on corrosion resistance was said to be due to the formation of soluble nickel complexes in the presence of high phosphorus leading to the removal of nickel from the film instead of the formation of the protective nickel hydroxide/nickel oxide film.

Chromium-Bearing Alloys. The Ni-Fe-Cr alloys can be subject to caustic SCC in hot, concentrated caustic. In deaerated 50% NaOH the presence of nickel improves the resistance to SCC. In aerated 50% NaOH both chromium and nickel need to be present to resist caustic SCC. The presence of molybdenum in these alloys was found to have no effect on the cracking resistance in deaerated 50% NaOH. Similarly, no particular heat treatment improved the resistance of these alloys to caustic SCC. The effect of temperature in the range tested, 284 to 332 °C (543 to 630 °F), was found to have only a minor effect on the extent of cracking (Ref 31). The beneficial effect of nickel in weaker deaerated caustic (10%) at 316 °C (601 °F) was found to be less pronounced with alloy 800, alloy 600, and alloy 690, all showing similar cracking resistance (Ref 65).

The most commonly used chromium-bearing nickel alloy is the basic Ni-Cr-Fe alloy 600 (76Ni, 16Cr, 8Fe; N06600). This alloy combines corrosion and heat resistance with excellent mechanical strength and workability. The high nickel content provides resistance to caustic corrosion. It is also resistant to chloride-induced SCC and to corrosion by many organic and inorganic acids and water should equipment be exposed to these environments external to the caustic application.

Alloy 600 (N06600) is the preferred alloy for NaOH service at higher temperatures, especially if sulfur compounds are present. The high chromium content of alloy 600 confers resistance to sulfur compounds and oxidizing environments in caustic. Alloy 600 (N06600) has performed well in alkaline sulfur solutions, such as those encountered in the manufacture of sulfate or kraft paper. However, sulfur contamination of nickel alloys can cause a form of LME-induced cracking at welding temperatures. This is not, in fact, true LME, but a form of intergranular penetration caused by the formation of a low-melting-point nickel/nickel sulfide eutectic. Alloy 600 is more resistant to this type of attack than is alloy 201 (Ref 14).

Minimal corrosion rates for alloy 600 are found in boiling NaOH up to about 50% concentration, as shown in Fig. 11 in comparison with alloy 201 (N02201) (Ref 66, 67). However, this alloy is subject to caustic SCC above about 190 °C (375 °F) in strong caustic, although short-term U-bend tests showed no cracks after 1 month in various solutions of caustic up to 70% at 184 °C (363 °F).

The possibility of SCC can be lessened if the alloy is fully stress relieved for 1 h at 900 °C (1650 °F) or for 4 h at 790 °C (1450 °F). In tests to assess the effects of heat treatment on SCC resistance, alloy 600 (N06600) and alloy 690 (N06690) were compared in 40% NaOH at 315 °C (600 °F). It was found that sensitized alloy 600 was more resistant to SCC than fully annealed alloy 600. The explanation given is that the chromium carbides present in the sensitized alloy have a more beneficial effect on SCC than the detrimental effect of chromium depletion. Effects of carbides and chromium depletion on IGA were not included in these tests. Resistance to SCC also increased with an increase in grain size and with chromium content (Ref 68).

Alloy 600 is used worldwide as a steam generator tube material in pressurized light water reactor nuclear plants where caustic SCC is also encountered. In this case, the environment is typically 10% NaOH at around 300 °C (570 °F) (Ref 69). Detailed information on the corrosion behavior of alloy 600 in nuclear reactor environments can be found in the articles "Corrosion in Pressurized Water Reactors" and "Effect of Irradiation on Corrosion and Stress-Corrosion Cracking in Light Water Reactors" in this Volume.

A variant of alloy 600 (N06600) is alloy 601 (N06601). This solid-solution-strengthened higher-chromium (23%) alloy was developed primarily for high-temperature applications. However, it too shows excellent corrosion resistance up to 98% caustic because of the high nickel content.

Fig. 11 Isocorrosion curves for alloy 600 (N06600) and alloy 201 (N02201) in caustic soda. Source: Ref 66, 67

The Ni-Cr-Mo alloys, such as alloy 625 (N06625) and alloy C-276 (N10276) are rarely employed in caustic service because the conventional nickel alloys are usually suitable. The improvement in corrosion resistance afforded by the high molybdenum content is minimal for all practical purposes in this service. Although not usually associated with alkaline service, these more expensive alloys may be usefully employed or encountered in some special applications. In 10% NaOH at 93 °C (199 °F), there was no measurable corrosion on alloy 625 (N06625). In boiling 50% NaOH at 143 °C (289 °F), a corrosion rate of 0.061 mm/yr (2.4 mils/yr) was measured on alloy 625, while on alloy C-276 the corrosion rate was 0.452 mm/yr (17.8 mils/yr) (Ref 61). The other chromium-containing nickel-base alloy that is sometimes used in caustic is alloy 690 (N06690).

The corrosion rate of VDM alloy 6030 (N06690) in 70% NaOH at 170 °C (340 °F) was 0.03 mm/yr (1.18 mils/yr). In the same tests alloy 400 (N04400) and alloy 33 (R20033) had the same corrosion rate, that is, 0.03 mm/yr (1.2 mils/yr), while alloy 59 (N06059) corroded at 0.48 mm/yr (18.9 mils/yr) and alloy C-22 (N06022) at 0.51 mm/yr (20.1 mils/yr) (Ref 70).

Clamps made from a proprietary nickel-base alloy with 16% Mo, 15% Cr, and W, holding internal steam coils in a reactor, failed by caustic SCC after three years service. The reactor environment consisted of 20% organics, 8% NaCl, 4% NaOH, balance water and the steam in the coils was at 180 °C (355 °F). It was postulated that the caustic must have become more concentrated under the clamps. An extensive investigation found that while the 22% Cr and 25% Cr duplex stainless steels were not immune to caustic SCC, they were much more resistant than the original nickel-base alloy. The failed clamps were replaced with a duplex stainless steel that is still in service after more than 12 years (Ref 71).

Copper and Copper Alloys

There is very little published corrosion data on copper alloys in caustic soda. This is because the major industries that use large amounts of caustic find copper contamination intolerable. For example, copper causes rancidity in soap and discoloration in rayon.

Copper, gunmetal (C90550), and bronze have limited resistance to caustic soda and potash as do copper-nickel alloys and high-tin aluminum bronze (Ref 72). High-zinc brasses suffer dezincification and should be avoided. However, conventional bronze castings, such as the 85Cu-5Sn-5Zn-5Pb (C83600) can be used for valves or pumps for 25% caustic solutions, for example. Bronzes solution annealed at 850 °C (1560 °F) can show SCC at pH 12.3 (about 500 ppm NaOH).

Corrosion resistance does increase with nickel content and the 90-10 cupronickel (C70600) and 70-30 grade (C71500) are sometimes used for

caustic service. Because of improved heat-transfer properties and strength, the 70-30 (C71500) grade has been used in evaporators up to 50% concentration in applications in which copper contamination is acceptable.

Copper piping has sometimes been used for caustic soda solutions in situations in which thermal stress relief of steel piping was impractical (Ref 17). In the absence of oxidizing agents (e.g., chlorites and chlorates), copper may be used up to 73% NaOH to 100 °C (212 °F). In molten caustic, however, copper is much less resistant than iron or nickel, being attacked at about 12.7 mm/yr (500 mils/yr) as compared with 0.51 mm/yr (20 mils/yr) and 0.18 mm/yr (7 mils/yr), respectively, for the alternative materials.

Titanium and Titanium Alloys

Titanium (e.g., grade 2, R50400) is a reactive metal that forms a thin, tenacious, self-healing oxide film in oxygen-containing environments. It resists alkaline media, including caustic solutions at subboiling conditions, but is not recommended for boiling concentrated solutions. Temperature and concentration limits for titanium are 80 °C (175 °F) and 50% NaOH. Titanium is at "high" risk for LME in caustic contaminated by mercury. Titanium is also rapidly attacked by hot caustic containing powerful oxidizing agents, for example, permanganate in pulp and paper applications.

Titanium and titanium alloys experience excessive pickup of hydrogen from corrosion reactions, causing hydride formation and possible hydrogen embrittlement in NaOH above 80 °C (175 °F) at pH of 12 or more (>400 ppm NaOH) (Ref 9). Corrosion of titanium increases rapidly as temperature increases, for example, the corrosion rate is 0.18 mm/yr (7 mils/yr) in 73% NaOH at 130 °C (265 °F), but is >1 mm/yr (>39.4 mils/yr) at 190 °C (375 °F).

Titanium finds application (subject to the limitations noted) chiefly where the surrounding media external to the caustic vessel or assembly contains impurities such as chloride, chlorate, hypochlorite, and wet chlorine. For example, titanium was not corroded in 10% NaOH + 15% NaCl at 82 °C (180 °F) or in 60% NaOH + 2% sodium hypochlorite + trace ammonia. In 50% NaOH containing free chlorine at 38 °C (100 °F), the corrosion rate was 0.023 mm/yr (0.9 mil/yr). The corrosion behavior of commercially pure titanium in various caustic solutions is shown in Table 15 (Ref 73, 74).

In a highly alkaline mixture of 52% NaOH and 16% NH₃ titanium corroded at >0.9 mm/yr (>35.4 mils/yr) in long-term tests at about 140 °C (285 °F). In 73% NaOH without ammonia the corrosion rate of titanium was only about 0.18 mm/yr (7.1 mils/yr) at about 130 °C (265 °F) (Ref 75).

In tests to assess the resistance of titanium and other alloys to caustic SCC at elevated

temperature, it was found that the corrosion rate was too high to detect discrete cracks in the specimens. These tests were carried out in 50% NaOH at temperatures in the range of 284 to 332 °C (543 to 630 °F) (Ref 31).

Zirconium and Zirconium Alloys

Zirconium (e.g., R60702) is a reactive metal, forming a very resilient oxide film (zirconia) that provides resistance to almost all alkalis, fused or in solution. The oxide film is self-healing and is protective up to 300 °C (570 °F). Zirconium has outstanding resistance to sodium hydroxide, tending to mirror the performance of nickel. Zirconium is considered useful in 73% NaOH at up to 138 °C (280 °F). Like titanium, zirconium is considered at high risk for LME in caustic contaminated with mercury. Zirconium is not attacked by oxidizing media unless chlorides are present (Ref 16).

Zirconium is very resistant to molten sodium hydroxide at temperatures above 1000 °C (1830 °F). It is resistant to SCC in boiling caustic solutions (Ref 9). Corrosion rates of zirconium Zr702 (R60702) in pure and contaminated caustic soda show that it is resistant to all conditions except very hot, very strong solutions (Table 16) (Ref 76).

Cast pumps and valves utilize the benefits of zirconium where service conditions are too severe for stainless steels, nickel alloys, or titanium.

Other Metals and Alloys

The common nonferrous metals, such as zinc, tin, and lead, are amphoteric and find no application in caustic service.

In ambient aqueous alkaline solutions, niobium has corrosion rates of less than 0.025 mm/yr (1 mil/yr). At higher temperatures, even though the corrosion rate does not seem exces-

sive, niobium is embrittled even at low concentrations (5%) of sodium hydroxide and potassium hydroxide. Like tantalum, niobium is embrittled in salts that hydrolyze to form alkaline solutions. These salts include sodium and potassium carbonates and phosphates (Ref 77).

Tantalum is destroyed in caustic solutions by the formation of successive surface oxide layers. The rate of attack increases with increasing concentration or temperature, and tantalum is dissolved in molten alkalis. Tantalum has, however, been used in dilute alkaline solutions (pH 10) in a paper mill (Ref 78). Ta-10W alloy showed passive behavior in 5, 10, and 15% NaOH at 50 °C (120 °F) and in 5% NaOH at 75 °C (165 °F). This Ta-10W alloy was found to be slightly more corrosion resistant than tantalum when both materials were in the passive state but less resistant under active corrosion conditions. The Ta-10W alloy can be used in caustic solutions only over a very limited range of concentrations at low temperatures (Ref 79).

Silver is probably the most resistant metal in caustic soda and is not attacked by sodium hydroxides at temperatures below 500 °C (930 °F). At one time it was used in the evaporation of anhydrous caustic.

Nonmetallic Materials

Elastomers. Some suggested temperature limits for rubbers and elastomers for immersion service in caustic soda solutions are given in Table 17. These data are a compilation from various sources.

Plastics. There are areas of use in which both thermoplastic and thermosetting resins find application in caustic service. They also find some application as immersion coatings, for example, modified epoxy-phenolics.

From a practical viewpoint, the majority of polymeric materials can handle caustic soda up to about 80 °C (175 °F). Careful attention needs to be given to the coating techniques or to fabrication involving polymeric materials. Factory-applied systems can usually be expected to be more reliable than those applied on site. Preparation of vessels to be coated should be carried out by competent companies to a recognized standard, such as NACE RP0178, "Fabrication Details, Surface Finish Requirements, and Proper Design Considerations for Tanks and Vessels to Be Lined for Immersion Service." Transport of coated components should be in accordance with the supplier's directives.

Some plastics, for example, hydrolyzable esters, are easily permeated by dilute caustic and are therefore more resistant in more concentrated (40 to 50% NaOH) solutions.

Thermoplastics. Polyolefins are inherently resistant to caustic, within their temperature limits. High-density polyethylene (HDPE) and polypropylene (PP) generally show better chemical resistance than low density PE. The HDPE

resists all concentrations of NaOH to 60 °C (140 °F). It should be noted that some copolymers are subject to environmental stress cracking (ESC) and that others, for example, PE/vinyl acetate (PVA) copolymers, are nonresistant because the PVA is subject to saponification. ASTM D 1693-05 provides a standard test method for evaluating ESC of ethylene plastics.

Generally, PVC, in rigid form, resists alkaline solutions to about 50 °C (122 °F). PVC-lined fiberglass-reinforced plastic (FRP) piping is used for caustic service, but unsupported PVC is not safe. For safety, the chlorinated polymer CPVC, which can tolerate 10 to 70% caustic at up to about 80 °C (175 °F) is often preferred. This limit for CPVC is not universally accepted, and some suppliers suggest much lower limits. Similarly, there are a range of limits suggested for polyvinylidene fluoride (PVDF) and some other polymers. When using any polymeric materials, it is advisable to consult the supplier and best to test the polymer under actual service conditions.

Table 18 shows some suggested temperature limits for thermoplastic materials in caustic service, as a compilation of several sources. Use of many of these materials is confined to linings for pipe and vessels, rather than as solid construction items, because of their lack of strength and the hazardous nature of caustic soda. Fluoroplastic materials are to be preferred, although PP-lined steel pipe has also been used to handle 50% NaOH at 90 °C (195 °F). Recommended temperature limits for plastic-lined steel pipes are given in Table 19 (Ref 80).

Thermoplastics are also used as the resistant liner in dual-laminate construction in which FRP is used as the reinforcing, structural element. The corrosion resistance of the FRP depends on the resistance of the thermoplastic liner, although resistant resins are often used in the construction of the FRP reinforcement in case of permeation and leaks in the thermoplastic liner. Most common thermoplastics are used in this type of construction, and many of them are suitable for use in caustic applications (Table 20) (Ref 81).

Thermosetting Resin Materials. The thermosetting resins are used almost entirely in reinforced construction, with the exception of modified epoxy coatings. Fiberglass-reinforced plastic is used for piping and equipment in caustic service, but not usually for high-concentration, high-temperature service (Ref 16, 82).

Such applications are contradictory to some extent in that the glass reinforcement is subject to attack by even quite weak alkalis. The use of FRP is effective because of the incorporation of special interior surface treatment, that is, the use of synthetic surfacing veils (polyesters and acrylics are common). The selection and protection of a highly resistant inner surface (the corrosion barrier) is critical for satisfactory service. The temperature limitations vary with the type of resin employed, and it should be noted that lower NaOH concentration applications may

be more aggressive to FRP than the stronger alkalis because of hydrolysis effects.

There are a great many resins used in conventional FRP construction. Conventional isophthalates and phenolic resins are not resistant to caustic and should not be considered. Some special formulations, such as bisphenol-A fumarate (Bis-A), are very good up to 50% caustic at about 80 °C (175 °F). The hydrogenated Bis-A is limited to dilute caustic at room temperature. Vinyl esters are also useful, although only in the lower concentrations at moderate temperatures. It must be emphasized that the chlorinated polyester (chlorendic anhydride) should not be used in NaOH.

Polyurethane shows variable performance in caustic limited by the permeability of the material; the lower the permeability of the polyurethane, the better the performance. This material is limited to 10 to 15% NaOH concentration. Epoxy resin formulations are widely used up to about 90 °C (195 °F). Furane (furfural-furfuryl alcohol) resins can be used both as reinforced materials (e.g., with graphite) and as coatings for immersion service in intermediate concentrations. They resist boiling 20% NaOH but not 5%. Cold-setting resins (as coatings for steel) have shown suitable resistance for up to 20% concentration NaOH even at the boiling point.

Temperature limits for applicable thermosetting resins in immersion service at various caustic concentrations are shown in Table 21 (data derived from various sources). The supplier should always be consulted in selecting thermoplastic or thermosetting construction for caustic service, and adequate consideration must be given to the mechanical and physical properties, particularly thermal expansion.

Carbon and Graphite

Corrosion resistance of carbon and graphite in caustic is good; impervious graphite, that is, graphite impregnated with carbon, not organic binders, is suitable for 80% NaOH up to 80 °C (175 °F) (Ref 83). The resistance of resin-impregnated graphite depends on the resins used. Graphite impregnated with phenolic resin is marginally resistant to 10 to 15% NaOH at up to

100 °C (212 °F). The furane-impregnated grade is rated at up to 50% NaOH at 130 °C (265 °F), and the grade that is impregnated with fluorocarbon is claimed to be acceptable at up to 80% or even 100% at up to 230 °C (446 °F) (Ref 84). Graphite impregnated with other resins are only slightly, or not at all resistant to >10% NaOH (Ref 83).

Impregnated raw graphite uses modified phenolic or furan resins under high heat and pressure. The phenolic binders and cements are attacked by caustic. Impervious graphite tube-and-shell heat exchangers contain cemented joints, which are traditionally made with phenolic resin for other services. It is essential that joints in equipment intended for caustic service be made with an epoxy or furane resin cement.

Impervious graphite is used for seals and gaskets because it has dimensional stability combined with self-lubricating, nonfatiguing, and noncontaminating properties.

Ceramics

Ceramics find practically no application in caustic service. Glass-lined vessels are only suitable for very low concentrations of caustic at very low temperatures, 1% or less at around 60 °C (140 °F) (Ref 85).

Rates of corrosion of borosilicate glass pass through a maximum at around 20% concentration at temperatures up to about 60 °C (140 °F). At higher temperatures, the maximum is at higher concentrations and corrosion rates at all concentrations increase dramatically.

Certain grades of silicon carbide can be used in caustic soda service. The rate of attack of silicon carbide (Hexoloy, Saint-Gobain Advanced Ceramics) and other ceramics are shown in Table 22. The weight loss rate is given in $\text{mg}/\text{cm}^2 \cdot \text{yr}^{-1}$, and a material with a rate of 0.3 to 9.9 $\text{mg}/\text{cm}^2 \cdot \text{yr}^{-1}$ is considered suitable for long-term service (Ref 86).

Corrosion in Contaminated Caustic and Mixtures

There are various kinds and degrees of contamination encountered in caustic soda produc-

tion and usage, and these may profoundly affect the corrosion resistance of the materials of construction commonly used in this service. There are some impurities inherent in the manufacturing process that are substantially removed during the refining process. In other instances, the caustic soda may be mixed with other process chemicals, either deliberately or inadvertently. This section discusses the effects of contamination of and by caustic and of admixtures of caustic with other chemicals.

Contaminants in Caustic Soda

Contaminants in caustic soda solutions derive from impurities in the feed brine, reactions occurring in the chlorine cell, or corrosion products formed during production, processing, shipping, or storing. Since the source of the caustic influences the purity of the product it could also affect the corrosiveness of the solution. A survey of producers, however, carried out by the National Association of Corrosion Engineers, found no substantial difference in the corrosion of steels or nickel alloys in 50 or 73% caustic soda derived from either mercury or diaphragm cells. The conclusion was that differences in concentration and temperature were more important than the manufacturing method used (Ref 87). This does not mean that all caustic soda solutions are equal in terms of their corrosion behavior, and the presence of impurities does influence the attack suffered by metals and alloys. Producers go to great lengths to either reduce aggressive impurities and/or to use materials that are more resistant to the type of caustic that they produce and concentrate.

Chlorates are produced at the anodes of the electrolytic cells and are strong oxidants. They are usually present at >100 ppm and have a beneficial effect on stainless steels and an adverse effect on nickel. It has been found that nickel pickup (from corrosion in the first effect evaporator tubing) was directly proportional to the chlorate content of the cell liquor, within the 120 to 200 ppm range encountered (Ref 88). Some plants add a continuous feed of 10% sucrose solution to react with this chlorate. No residues are left from this reaction, and product quality is not compromised (Ref 89). More commonly, the chlorate is removed before or during evaporation by proprietary treatments or by extraction with ammonia, which also reduces the dissolved salt (Ref 14).

Chlorate ions can increase the rate of corrosion of carbon steel. For 48% NaOH with 0.5% NaClO_3 , carbon steel showed a tenfold increase

in corrosion rate compared with caustic that did not contain chlorate ions (Ref 90). Chlorates also increased the corrosion rate of nickel alloys (Ref 14).

Corrosion of nickel in the caustic plant is ascribed either to chlorate ions (ClO_3^-) or to hypochlorites (OCl^-). General corrosion rates can exceed 0.5 mm/yr (20 mils/yr). Corrosion is aggravated by high velocity, as over welds on pump discharge piping. Velocity and increased temperature are thought to be the most probable cause of attack of nickel in caustic service, rather than chlorate or hypochlorite levels. In laboratory tests at 185 °C (365 °F) in actual first effect caustic liquor (43% NaOH, 0.15% ClO_3^-) and in a synthetic mix (51% NaOH; 0.20% ClO_3^-) corrosion and SCC resistance of alloys 200 and 26-1 were both superior to any of the other alloys tested. The relative corrosion resistance of the other alloys in static and circulating simulated and actual liquors was:

alloy 600 \gg alloy 825 \cong alloy 800 \cong alloy 28

Some of these data are summarized in Fig. 12, which shows that chlorates increase the corrosion of nickel and nickel alloys, although the effect is not sufficient to cause failures of nickel in evaporators without the presence of additional

Fig. 12 Effect of nickel content on corrosion of various materials in simulated first effect liquor at 185 °C (365 °F). Source: Ref 91

factors, such as temperature or velocity. Increased nickel content in the alloys increases the corrosion resistance, particularly in caustic without chlorates. Alloy 26-1, which has no nickel, has good corrosion resistance but can suffer from SCC in boiling solutions of >30% NaOH and can also be subject to IGA. The presence of hypochlorites was found to increase the corrosion rates of all the alloys to a lesser or greater extent (Ref 91).

The effect of sodium chloride and sodium chlorate additions to hot caustic soda solutions on the corrosion of the ferritic stainless steel, E-Brite (S44627), is shown in Table 23 (Ref 29). The corrosion rate of this alloy is little affected by these contaminants, common in cell liquors, unlike that of nickel in which the corrosion rate is accelerated. This alloy is attacked in hotter, stronger caustic solutions as shown in the data for 70% NaOH at 188 °C (370 °F) that is included in this table (Ref 92). Corrosion is decreased in caustic by the addition of sodium chlorate and hypochlorite up to 1000 ppm, but IGA occurred when these additions were at 10,000 ppm.

The effect of chlorides and chlorates on the corrosion resistance of another ferritic alloy, Sea-Cure (S44660), in hot caustic soda solutions is shown in Table 24 (Ref 93). These data compare the behavior of this alloy with that of type 316, ferritic stainless steel 26-1S, and pure nickel. These data show that Sea-Cure is as resistant to these conditions as is alloy 200, except for the tendency to IGA in this environment.

The effects of the presence of chlorides and chlorates was investigated for a duplex stainless steel (S32906) and alloy 200 (N02200). These data show that when higher levels of chloride and chlorate are present, simulating membrane and diaphragm caustic, the duplex alloy is much more resistant than nickel (Table 25) (Ref 36).

Chlorides. Because NaOH is produced by electrolysis of brine, chlorides may be present from about 20 to 5000 ppm, the minimum concentration being typical of membrane cell caustic. Chlorides in caustic soda solution do not cause chloride SCC of austenitic stainless steels. A solution of 0.5 g/L NaOH at pH 12 is sufficiently alkaline to avoid this type of cracking, which is common in neutral or acidic solutions (Ref 9). It has also been claimed that chlorides

inhibit caustic SCC. Mercury cell caustic typically contains 20 to 30 ppm chlorides, while diaphragm cell caustic is more likely to contain up to 1% chlorides. While chloride-contaminated caustic soda solution may not cause SCC of austenitic stainless steel if the caustic soda is consumed, for example in a neutralizing process, then the residual neutral chloride-containing solution may then initiate cracking (Ref 14). See Table 23 for the effect of chlorides with and without chlorates on the ferritic E-Brite stainless steel (S44627), Table 24 for Sea-Cure (S44600), and Table 11 for the effect of chlorides on alloy 28.

Zirconium is resistant to sodium hydroxide solutions even when high levels of chlorides are present (see Table 16).

Alloy 800 (N08800) was tested in a NaOH cooling tank at 70 to 105 °C (160 to 220 °F) for 119 days. The environment was 50% NaOH with 10 to 15% NaCl, and the corrosion rate measured was negligible at <0.003 mm/yr (<0.12 mil/yr) (Ref 94).

Chlorine/Hypochlorite. Hypochlorites are formed when chlorine is introduced into water or alkaline solutions:

Sodium hypochlorite (NaOCl) is liable to initiate pitting in otherwise passive metals because of the concentration cells between freely exposed and occluded surfaces, analogous to an oxygen concentration cell.

The corrosion resistance of various alloys in caustic soda containing chlorine was tested in field trials. The results of these tests showed that alloy 33 (R20033) performed better than the other alloys tested (Table 26) (Ref 95). All of the alloys showed acceptable corrosion rates in the liquid and the vapor, although pitting and crevice corrosion, severe in cases, was observed.

Mercury can be entrained from the production source, while mercuric ions can be reduced to metallic mercury at local cathode sites. Metallic mercury contamination can lead to LME or liquid metal cracking (LMC) in some alloy systems. Titanium and zirconium and their alloys, copper and copper alloys, aluminum and aluminum alloys, alloy 400, and alloy 200 at elevated temperatures are known to be at risk from this form of attack (Ref 96).

Table 24 Corrosion rates of various alloys in hot caustic solutions

Alloy	Corrosion rate					
	in 55% NaOH + 8% NaCl + 0.3% NaClO_3 at 99 °C (210 °F)		in 50% NaOH at 143 °C (290 °F)		in 55% NaOH + 8% NaCl + 0.3% NaClO_3 at 158 °C (315 °F)	
	mm/yr	mils/yr	mm/yr	mils/yr	mm/yr	mils/yr
316	0.15	5.9	0.38	15.0	Very high	Very high
26-1S	<0.0025	0.1	0.015	0.59	0.02	0.79
Alloy 200	<0.0025	0.1	0.023	0.91	0.07	2.8
Sea-Cure	<0.0025	0.1	0.025	1.0	IGA	IGA

IGA, intergranular attack. Source: Ref 93

Sulfur. Sulfides, sulfite, or sulfate contaminants in caustic can increase the rate of corrosion of carbon steel if the passive oxide film on the steel is damaged, scratched, defective, and so forth. In considering low-alloy steels for service in the cellulose and paper industry, where strongly alkaline solutions often contain sulfide, it has been found that sodium sulfide and sodium thiosulfate exacerbate damage, whereas sodium sulfite/sulfate have little effect (Ref 97).

Sulfur species can also accelerate the corrosion of nickel alloys, especially at elevated temperatures.

Iron. Because much of the processing, storage, and transportation of caustic soda is effected in steel, iron contamination is often present, either as the soluble ferroite or ferroate, or as fines of colloidal ferric oxide. The resultant discoloration is objectionable for many applications, notably the soap/detergent, pulp/paper, and rayon/textile industries. More resistant materials of construction are often selected just to prevent this undesirable contaminant.

Soda Ash

Soda ash is anhydrous sodium carbonate (Na_2CO_3) chemical abstracting service (CAS) number 497-19-8. It exists as a naturally occurring mineral in parts of Africa and in the United States, notably in Wyoming. Native soda ash is found in the form of trona, which is sodium carbonate and bicarbonate, or as brines that are

mixtures of sodium carbonate, sulfate, and sulfite (Ref 98). Soda ash can be produced by the reaction of caustic soda and carbon dioxide or in the Solvay (ammonia soda) process that reacts limestone, ammoniated brine, and coke.

Soda ash is used in household cleaners (washing soda), glass making, water treatment, chemical processing, and so forth. In some pulp and paper applications, soda ash is reacted with limestone to produce caustic soda, used in neutralizing and other processes.

Pure soda ash is a hygroscopic white powder whose molecular weight is 105.99 and specific gravity 2.533. It has a melting point of 851 °C (1564 °F) and generates heat of solution in water. It has a strong degree of alkalinity.

Sodium carbonate decahydrate ($\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$) melts at 34 °C (93 °F) to form a solution of about 37% concentration. Corrosion problems may develop because it can either lose carbon dioxide to release free caustic or further absorb CO_2 to form the bicarbonate (NaHCO_3).

Sodium carbonate at elevated temperature will cause caustic corrosion in a manner similar to caustic soda corrosion. The propensity to caustic SCC is less with soda ash, and carbon steel is routinely used to handle boiling solutions. The alkalinity of soda ash is less than that of NaOH, and the carbonate ions have an inhibiting effect on many metals. Soda ash can form bicarbonate, and this may corrode steel because of its lower pH (Ref 16).

A typical application is the use of sodium carbonate solutions for the absorption and release of carbon dioxide from hydrocarbon streams, in a manner analogous to alkanolamine acid gas scrubbing systems. The carbonate reacts selectively with CO_2 to form bicarbonate, which is reheated in the separation column to release the acid gas, returning the regenerated lean Na_2CO_3 solution to the absorber. This process is inherently corrosive to steel, particularly in the regeneration step.

Potassium Hydroxide

Potassium hydroxide (KOH), CAS 1310-58-3, is very similar to sodium hydroxide in its

chemical and corrosion characteristics, but it is much less common. Caustic potash is produced in a similar manner to caustic soda by the electrolysis of potassium chloride. The equipment for evaporation is largely based on nickel and nickel alloys with cathodic protection being employed for >50% KOH solutions, which have a higher boiling point than NaOH.

Corrosion data are limited, but KOH corrosion behavior is similar to that of NaOH, and can be extrapolated from the NaOH data and experience. Caustic SCC can occur in caustic potash solutions at elevated temperatures, but cracking is not so severe in the potassium salt for alloy 400 and alloy 600. The failure of a low-carbon steel (ASTM A516, grade 70) pressure vessel after 10 years service in a hydrogen sulfide absorber was diagnosed as due to caustic SCC from KOH. The environment was 20% aqueous KOH, potassium carbonate, and arsenic at 33 °C (91 °F). Although the operating temperature was low for SCC, the vessel had been exposed to a fire that may have taken the temperature above the induction temperature. It may also have increased the local concentration of KOH and added stress to the existing residual and operating stresses (Ref 99).

In a problem analogous to that which occurs with caustic carryover in steam, SCC of type 347 (S34700) by potassium hydroxide has been reported. In one plant, a catalyst containing potassium oxide was to be used in a hydrogenator. When the plant was started up with 300 °C (570 °F) steam after a catalyst change, sufficient KOH was formed and entrained to cause failure of the stainless equipment downstream.

Some data are available for alloy 200 in caustic potash under velocity conditions and when mixed with potassium chloride (KCl) and potassium chlorate (KClO_3) (Table 27) (Ref 100).

Data for various metals and alloys in KOH are shown in Table 28 (Ref 101). This table shows that KOH at these temperatures and concentrations is not very corrosive even to low-carbon steel.

Zirconium has a corrosion rate of <0.025 mm/yr (<1 mil/yr) in 0 to 50% KOH

Table 25 Corrosion rates of S32906 and N02200 in boiling NaOH solutions simulating membrane and diaphragm cell liquors

Corrosion by Ammonia

Michael Davies, CARIAD Consultants

ANHYDROUS AMMONIA (NH_3) is a major commercial chemical that is used in the manufacture of fertilizers, nitric acid (HNO_3), acrylonitrile, and other products. The world total production of NH_3 in 1996 was 93,500 thousand metric tons of nitrogen. In 2002, according to the International Fertilizer Association, the world production was 108,320 thousand metric tons (89,025 thousand metric tons of nitrogen). Approximately 80% of the U.S. apparent domestic NH_3 consumption was for fertilizer use, including anhydrous NH_3 for direct application, urea, ammonium nitrate (NH_4NO_3), ammonium phosphates, and other nitrogen compounds.

Ammonia is made by a number of processes; the two principal ones are:

- Steam reforming of natural gas or other light hydrocarbons (natural gas liquids, liquefied petroleum gas, naphtha). Modified steam reforming using excess air in the secondary reformer and heat-exchange autothermal reforming are also being used to some extent.
- Partial oxidation of heavy fuel oil, coal, or vacuum residue is used.

The hydrogen-containing gas from the primary reformer is mixed with nitrogen in the secondary reformer to produce a gas containing CO_2 , H_2 , and N_2 . The CO_2 is stripped off, and the remaining synthesis gas (syngas) is reacted over an iron catalyst to produce NH_3 that is condensed and separated from the gas stream. Ammonia that leaks into cooling towers can be converted to HNO_3 by nitrifying bacteria and pose a corrosion threat throughout the plant. Since much of the NH_3 production process operates at elevated temperatures, materials resistant to high-temperature corrosion and with sufficient mechanical strength are needed. The anhydrous NH_3 is purified and shipped or stored, usually in steel tanks.

Liquid anhydrous NH_3 is stored in one of three ways, selected on economic grounds (Ref 1, 2):

- Flat-bottomed steel storage tanks are used for storing very large volumes of NH_3 , with typical capacity of 10,000 to 30,000 tons (up to 50,000). These tanks are designed for low pressure so the anhydrous NH_3 must be fully

refrigerated at atmospheric pressure and at the atmospheric boiling point of -33°C (-28°F).

- Semirefrigerated tanks or spheres are used where larger volumes of NH_3 must be stored. These are held at some intermediate temperature, for example, -12°C (10°F), between ambient and fully refrigerated -33°C (-28°F) conditions. Cylindrical storage vessels (bullets) are also commonly employed.
- Pressurized tanks (around 2 MPa, or 300 psig) at ambient temperature in spheres or horizontal cylinders up to about 1700 tons are also used.

Ammonia and ammonium hydroxide (NH_4OH) are not particularly corrosive in themselves, but corrosion problems can arise with specific materials, particularly when contaminants are present. Air or oxygen contamination is a factor in many instances, causing general corrosion of some materials and localized corrosion, specifically stress-corrosion cracking (SCC), in others. Contamination with carbon dioxide can lead to corrosion due to carbamates, which are sometimes encountered in NH_3 recovery systems. High-temperature corrosion will occur in hot dissociated NH_3 .

Aluminum Alloys

Aluminum and its copper-free alloys show good resistance to dry, gaseous NH_3 at ambient or elevated temperatures. Corrosion rates of <0.025 mm/yr (<1 mil/yr) at 21°C (70°F) and <0.05 mm/yr (<2 mils/yr) at 100°C (212°F) are typical (Ref 3).

Aluminum may be used for cargo tanks for the anhydrous product. If moisture is present there is some attack on aluminum, but a protective film soon forms and corrosion stops. Aluminum tubing is used in NH_3 refrigeration units operating in liquid NH_3 containing 5% water. In moist NH_3 vapor, corrosion is low (<0.1 mm/yr, or 3.9 mils/yr) below about 50°C (120°F). Under condensing conditions of steam and NH_3 , aluminum can be attacked and the rate does not decrease with time. Attack is prevented if the CO_2 -to- NH_3 ratio is at least 2.5 to 1. This high level of carbon dioxide can be achieved, for

example, in NH_3 recovery plants by the decomposition of alcohols or other organic chemicals. Hydrogen sulfide also inhibits corrosion under condensing conditions. Aluminum is used for compressors, heat exchangers, evaporators, condensers, and piping in the production of NH_3 . Aluminum pressure vessels are used in the storage and transport of NH_3 (Ref 4).

There is mild action on aluminum in NH_4OH solutions at temperatures below about 50°C (120°F). The greatest attack occurs in concentrated solutions (around 25%) and at about 5% concentration. For aluminum to perform well in NH_4OH the solution must be free from heavy metals and halogen ions. Attack is limited if the solution is saturated with aluminum ions before exposure takes place. As with anhydrous NH_3 , aluminum is attacked at higher temperature, but this attack stops as a protective film forms (Ref 5, 6). Even at ambient temperature, corrosion rates decrease with time of exposure (Ref 7).

The initial attack of aluminum by dilute NH_3 solutions (up to ~10%) is controlled by the diffusion of OH^- ions to the surface and is a function of pH. The surface is passivated once sufficient corrosion product has been produced to form a protective film. Under some exposure conditions, the corrosion product may continue to dissolve rather than form a protective film (Ref 4).

Iron and Steel

Ferrous alloys are generally not corroded by NH_3 or NH_4OH at ambient or elevated temperatures. Corrosion can, however, occur in the presence of contaminants and ferrous alloys can be subject to SCC.

Cast Irons

Cast iron has been widely used in NH_3 production and handling. Since it is generally thick walled, somewhat higher corrosion rates can be tolerated as long as the iron in solution is acceptable. Cast iron strippers have been used to concentrate crude gas liquors with about 1 to 2% NH_3 up to 25% NH_4OH . A corrosion rate of 1 mm/yr (40 mils/yr) has been found in the

vapor space of a ductile cast iron NH₃ pressure distillation plant operating at about 88 °C (190 °F). White cast iron with >18% Cr content (ASTM A532 grade IID) has been used in some applications.

High-nickel cast irons have been used in valves, pumps, and so forth, in NH₄OH solutions. Austenitic nickel cast iron NiResist cooling coils corroded at about 0.005 mm/yr (0.1 mil/yr) at 25 °C (75 °F) and 0.15 mm/yr (5.9 mils/yr) at 70 °C (160 °F) in flowing NH₃ gas (Ref 3). Laboratory testing of NiResist (International Nickel Company) cast irons and unalloyed cast irons gave the results shown in Table 1 (Ref 8). This table also shows data from NH₃-containing environments in industrial applications. In most applications unalloyed cast iron is at least as good as the NiResist irons, but in the concentrated and contaminated solutions the alloyed irons are superior. In most cases in this table, the recommended NiResist irons are types 1 (F41000) and 2 (F41002) with type 3 (F41004) also appropriate for the dilute solutions.

Carbon Steels

Ammonia is essentially noncorrosive to steels at ambient temperatures, which accounts for their widespread use. Carbon steels (commonly referred to as "steels" in many standards and regulations pertaining to NH₃ storage and transport) include both carbon steels and carbon-manganese steels and are commonly specified for process equipment. These alloys are by far the most commonly used materials for the storage and handling of NH₃. The standard used to specify the steel is selected based on the mechanical properties required by the application, with consideration of environmental factors.

Even at elevated temperatures, corrosion rates in anhydrous NH₃ are low, less than 0.05 mm/yr (1.9 mils/yr) in the range from 297 to 589 K (24 to 316 °C, or 75 to 600 °F) (Ref 9). One very important exception relative to corrosion resistance of steels is the tendency of anhydrous NH₃ to cause SCC (see below).

Ordinary carbon and alloy steels are satisfactory in NH₄OH service, although a superficial rusting will occur in the vapor space.

Stress-Corrosion Cracking of Steels. Ammonia SCC in carbon steel vessels was first reported in the mid-1950s in agricultural service tanks. Cracking occurred in areas of high residual stress, such as welds and cold-formed dished heads. Hot forming or stress relieving the heads considerably reduced the occurrence of cracking, as did the addition of a small amount of water to the NH₃.

Throughout the 1960s and early 1970s, cracking problems appeared to be mainly associated with high-strength quenched-and-tempered steels. Later, there were reports of cracking occurring in spheres containing anhydrous NH₃ with water additions and also

in spheres that had been stress relieved after finding and repairing cracks.

The cause of this cracking is now accepted to be high local stresses and the presence of air contamination, although nitrogen and carbon dioxide are also thought to play a role. Cracking is accelerated by the use of high-strength steels, the presence of hard welds and air contamination (Ref 4, 10). The highest susceptibility to SCC has been found to be in liquid NH₃ with 3 to 10 ppm oxygen and a water content <100 ppm. Stress-corrosion cracking can occur, however, in NH₃ with an oxygen content down to 0.5 ppm when the water content is very low (Ref 11).

Possible ways to control or reduce liquid NH₃ SCC in carbon steels include (Ref 12):

- Eliminate oxygen
- Add around 0.2% water to the NH₃
- Use steel with an actual yield strength less than 300 MPa (44 ksi)
- Reduce residual stress by stress relieving
- Inspect often enough to detect cracks before they grow to dangerous proportions
- Use a sacrificial anode, such as a thermal sprayed zinc coating
- Cathodically protect the steel
- Use a different material such as stainless steel

- Paint the steel with a suitable protective coating

Some of these options are impractical at the present time (2005) since:

- There is no commercially available paint suitable for NH₃ submersion duty.
- Using stainless steel would increase the capital cost of vessel construction by at least 100% and increase steel mass.
- Cathodic protection has not yet been shown to be reliable in refrigerated installations and would not protect in vapor spaces, for example, in road tankers.
- Zinc thermal spraying of NH₃ tank internals has been used, largely on a trial basis. More experience is required.

The remaining options that are currently used for storage vessels or road tankers are evaluated in Table 2 (Ref 12).

Stress-corrosion cracking of carbon steel occurred in NH₃ receiver tanks used for recycling NH₃ in a urea plant. These tanks (SA 516 grade 70) suffered extensive cracking in welds and HAZ in spite of the addition of 0.2% water to the system. It was concluded that the water was not uniformly distributed throughout these vessels and was, probably inadequate to

Table 1 Corrosion data for NiResist and unalloyed cast iron in NH₃ solutions and environments

Medium	Temperature		Average corrosion rate for:			
			Cast iron		NiResist	
	°C	°F	mm/yr	mils/yr	mm/yr	mils/yr
5% NH ₄ OH	15.6	60	Nil	Nil	<0.01	0.01
10% NH ₄ OH	15.6	60	Nil	Nil	<0.01	0.2
25% NH ₄ OH	15.6	60	Nil	Nil	<0.01	0.18
50% NH ₄ OH	15.6	60	Nil	Nil	Nil	Nil
75% NH ₄ OH	15.6	60	Nil	Nil	Nil	Nil
Concentrated NH ₄ OH	15.6	60	0.05	2	Nil	Nil

Source: Ref 8

Table 2 Ammonia SCC mitigation measures

Corrosion mitigation scheme	Refrigerated tanks	Road tankers
Eliminate oxygen	This is a normal commissioning procedure, but regular inspection reintroduces oxygen. The number of inspections should be minimized, on-line inspection is desirable.	Not usually practical
Passivate ammonia with 0.2% water	This is now normal practice.	Vapor space not protected
Use steel with <300 MPa (<44 ksi) actual yield strength	Most tanks are constructed of grade 490 steel (ASTM A515 or equivalent) so actual yield easily exceeds 300 MPa (44 ksi).	Tankers in Australia are often made of quenched and tempered steel where yield >600 MPa (>87 ksi) to reduce tare weight.
Stress relieve	Not practical	Mandatory, especially where yield > 300 MPa (> 44 ksi) which is almost always.
Inspect regularly	Traditionally, tanks were shut down to inspect. Inspection on-line now becoming more possible and used.	Inspection is mandatory, usually every one or two years.

Source: Ref 12

protect the vapor space in the condensing NH_3 (Ref 13).

Nitriding of Steels. At high temperatures, NH_3 may dissociate into hydrogen and nascent nitrogen. The nascent nitrogen has a high affinity for iron and reacts to form a very hard, brittle metal nitride. This is sometimes a desirable reaction, and wear-resistant surfaces are commonly produced on steel parts by nitriding in an NH_3 atmosphere.

Although commercial nitriding is performed at temperatures above the normal service temperature for steels (495 to 565 °C, or 925 to 1050 °F), significant nitriding can occur at lower temperatures, resulting in loss of ductility. Ammonia dissociation is catalyzed by iron, which also contributes to the damage potential. For these reasons, steels are restricted to use at temperatures below 300 °C (600 °F) in NH_3 service. In NH_3 converters, nitriding layers can develop over time to a depth of several millimeters and these hard layers can cause brittle, surface cracks to form. Austenitic steels, in converter baskets for example, develop thin, hard nitrided layers that tend to flake off (Ref 1). Nitriding of pipes, grid supports, and so forth in the NH_3 converter is limited by using stainless steels with a higher nickel content, for example, type 347.

Hydrogen Attack. At high temperatures and pressures, hydrogen that is present in NH_3 synthesis can dissociate; the atomic hydrogen entering the steel lattice reacts with carbon to form methane (CH_4). This weakens the steel in two ways, by removing carbon from the steel (decarburization) and by forming blisters or fissures in so doing. This can eventually cause the vessel or pipe to rupture, often without any obvious prior deformation. Areas around weld seams are particularly prone to this phenomenon.

The risk of attack may exist at temperatures as low as 200 °C (390 °F) and hydrogen partial pressure as low as 7 bar (700 kPa). Selection of appropriately resistant materials can largely eliminate this problem. The classic Nelson curves described in the American Petroleum Institute (API) document 941 (Ref 14) give guidance on the stability limits of various alloys in terms of temperature and hydrogen partial pressure. These original guidelines have been modified in recent years on the basis of ongoing experience. For example, the low-alloy steels with 0.25 and 0.5% Mo are now classed as unalloyed steels from the viewpoint of resistance to hydrogen attack (Ref 1).

Steels with low levels of molybdenum and no chromium failed in a number of cases in catalytic reforming service, so care was recommended in the use of these alloys for that application. However, failures caused by hydrogen also occurred in hydrosulfurization, NH_3 synthesis, and other parts of NH_3 production plants, leading to their removal from these safe operating charts (Ref 15). Curves (modified from Nelson curves) that incorporate findings from the extensive operating experience are available that provide safe operating conditions for carbon and low-

alloy steels (Ref 14, 16). An example of a modified Nelson curve is shown in Fig. 1.

The standard chromium-molybdenum steels are being modified and improved so that they can be used at higher temperatures. A modified 2 $\frac{1}{4}$ Cr-1Mo has been developed that is usable at temperatures up to 484 °C (903 °F) instead of being limited to 454 °C (849 °F) as are conventional steels of this type. This higher-temperature operation is permitted under ASME II rules. The modification included the addition of $\frac{1}{4}\%$ V. The API 941 standard has placed this modified steel at the same limits in terms of temperature and hydrogen as the 3Cr-1Mo steel. The first vessel made from this steel was an NH_3 converter fabricated in 1995. The vanadium-modified steel also has a better resistance to temper embrittlement than does the standard, unmodified version (Ref 16).

Hydrogen damage can also occur from the dissociation of molecular hydrogen into atomic hydrogen at elevated temperatures. Atomic hydrogen can diffuse into metal structures and recombine into molecular hydrogen at defects or discontinuities within the metal. This is also known as hydrogen embrittlement and is usually associated with welds that have not received correct postweld heat treatment (PWHT). In contrast to the phenomenon described above, this effect of hydrogen is reversible and hydrogen can diffuse back out of the structure if held at atmospheric pressure at around 300 °C (570 °F). Slow cooling from elevated-temperature and pressure operation is often recommended to permit this diffusion process to occur.

Temper Embrittlement. If heat-resistant steels are held at tempering temperatures, that is, above about 400 °C (750 °F), for long periods their impact properties can decline. The transition temperature between ductile and brittle behavior can be elevated to 60 °C (140 °F) from the normal 0 °C (32 °F) or below. This tendency to embrittle can be reduced by controlling the

level of trace elements (Si, P, Mn, Sn) in the steel. In this respect, modern steels are generally much cleaner than some of the older steels and are less prone to this phenomenon. Vessels or pipes in which temper embrittlement is anticipated should not be pressurized at low temperatures.

Hydrogen Sulfide Attack. Most high-temperature steels are attacked by hydrogen sulfide (H_2S) in the gas stream in partial oxidation plants. The use of austenitic stainless steels eliminates this problem, but stress relief of welds is advised in these plants to avoid SCC by chlorides sometimes present in the feed oil (Ref 1).

Corrosion can also occur from the condensation of sulfur acids at the colder ends of flue gas ducts. Type 304 stainless steel is used at the cold ends. Carbon steel air preheater tubes in this area can corrode. Alternative materials include cast iron, glass, or coated steel.

Alloy Steels

Steels alloyed with small amounts of chromium, molybdenum, nickel, or other elements are referred to as low-alloy steels, and they can provide an economical alternative to high-alloy steels at both high and low temperatures. Low-alloy steels have been used effectively in NH_3 storage vessels. These steels are also subject to SCC with high stresses and air contamination being the main factors causing cracking. The addition of 0.1 to 0.2% water inhibits this attack (Ref 4). Chromium-molybdenum steels are the most common steels of this type used in NH_3 applications.

Chromium-molybdenum steels are commonly used at elevated temperatures where the alloying additions provide resistance to hydrogen attack and increase the strength of the alloy. Typical alloys are 1.25Cr-0.5Mo (K11597), 2.25Cr-1Mo (K21950), 5Cr-0.5Mo (K41545),

Fig. 1 Modified Nelson curve showing the operating limits for steels in hydrogen service. Source: Ref 14

7Cr-0.5Mo (S50300), and 9Cr-0.5Mo (S50400). Their use in NH_3 service is chiefly in NH_3 synthesis, the alloy selection being based on API Publication 941 (Ref 14). Old editions of this standard have curves showing the resistance of low-alloy steels, with 0.5% Mo without chromium. As mentioned previously in the section "Hydrogen Attack," service experience has shown that this alloy has little more resistance to hydrogen attack than carbon steel so the API publication was updated in 1991 to reflect this experience. Other uses for these chromium-molybdenum steels are in high-strength parts such as fasteners.

Nickel Alloy Steels. Addition of nickel to steel greatly enhances the low-temperature toughness (impact properties). For this reason, these materials are sometimes specified for low-temperature NH_3 service, especially as weld filler metals. Typically, the nickel-alloy steels contain 3.5% (K32025), 6%, or 9% Ni (K81340).

Stainless Steels

From the point of view of corrosion, stainless steels are not normally required in NH_3 , but they do find many applications, particularly for low temperatures and to avoid iron contamination. All grades of stainless steel are resistant to NH_4OH solutions at up to the atmospheric boiling point.

Ferritic Grades. The standard ferritic grades are rarely used in NH_3 service, but the modern superferritic steels find occasional applications. The first superferritic steels were based on 26% Cr, 1% Mo (S44627), and the niobium-stabilized XM-27 (S44627). These were developed to provide better resistance to chloride SCC than the austenitic 300 series. Superferritic steels include AL 29-4C (Allegheny Ludlum Corporation) (S44735), AL 29-4-2 (Allegheny Ludlum Corporation) (S44800), Sea-Cure (Plymouth Tube Co.) (S44660), and Monit (Uddeholm, originally; now, Outokumpu Stainless) (S44635). The superferritic AL 29-4C (S44735) has been used successfully in an NH_3 stripper-reboiler handling water, NH_3 , H_2S , and steam (Ref 17).

Precipitation-Hardening Grades. The PH stainless steels see limited service in NH_3 environments, but play an important role nonetheless. These alloys exhibit very high strengths combined with good notch toughness and corrosion-resistance properties. For this reason, they are often the preferred material for such parts as valve stems and certain critical fasteners. Some of these alloys are susceptible to hydrogen embrittlement in corrosive or hydrogen-rich environments.

Duplex stainless steels are not used in NH_3 service except where their resistance to chloride SCC is useful from the water side of heat exchangers. The modern grades, for example, alloy 2205 (S31803), typically also contain molybdenum to achieve a composition of about 22% Cr, 5.5% Ni, 3% Mo, and 0.03% C max.

They are strengthened and stabilized by nitrogen. The mixed austenite-ferrite structure imparts strength and resistance (but not immunity) to chloride pitting and SCC. The duplex 3RE60 (S31500) has been used to replace standard austenitic stainless steels in this type of situation. The duplex stainless steels have higher strength than the lower austenitic grades such as type 304 (S30400), but are subject to temper embrittlement at about 475 °C (885 °F).

Welding tends to lead to variations (20 to 80%) in the austenite/ferrite ratio in the as-cast weld bead and fusion zone. To minimize this effect, they are welded with a nickel-rich, over-matching rod.

Austenitic Stainless Steels. The standard austenitic grades, for example, types 304 (S30400) and 316 (S31600), find widespread use in NH_3 service since they are resistant to general corrosion and NH_3 SCC. Stabilized and low-carbon grades are not generally needed in NH_3 applications. Type 304 (S30400) stainless steel was found to be resistant to intergranular attack (IGA) in 28% NH_3 solution at room temperature even after sensitizing for 1 h at 677 °C (1250 °F) (Ref 18). Stainless steels can, however, fail by SCC that is initiated by sensitization formed during heating, for example when welding. Such a failure in a reformer tube occurred at the welded junction between the type 321 flange and HK-40 catalyst tube. The weld and HAZ were sensitized when joined using a high-carbon welding rod. The high-nickel alloy weld that was intended to protect the cast steel (HK-40) from corrosion had inadvertently been machined off, thus exacerbating the corrosion (Ref 19). Fuel gas lines that contain H_2S (stripped from feedstock naphtha) are subject to corrosion. The use of steam-traced type 304 limits this problem.

The high cost of stainless steels relative to carbon and low-alloy steels often precludes their use for large equipment, but their many advantages lead to their selection for smaller parts and components. They are used in low-temperature service since they have an extremely low nil-ductility transition temperature (NDTT) and exhibit excellent notch toughness at temperatures far below the atmospheric boiling temperature of NH_3 . In elevated-temperature services in NH_3 synthesis, they are used because of their resistance to hydrogen attack and nitriding. Start-up heater coils in the NH_3 synthesis section are vulnerable to high-temperature corrosion and fatigue. Usually, type 321 performs well here.

Some shallow nitriding does occur after years of service in aggressive environments, but due to the excellent notch toughness of the base material, this effect does not reduce the structural integrity. Another common area of application of the basic grades is in heat-exchanger tubes, where the material selection is influenced by the fluid used to heat or cool the NH_3 .

These standard grades can suffer from chloride SCC, particularly in partial oxidation plants in which the feed oil contains chlorides. Chloride SCC failures can also occur under upset

condition. An example of such a failure occurred in type 321 and 310S tubes in a waste heat boiler in an ammonium synthesis converter. The direct cause of this SCC was the failure of a feedwater boiler pump that was not repaired or replaced and permitted a buildup of deposits in the system. General and intergranular corrosion was also observed on these tubes (Ref 20).

There are many more specialty grades of stainless steels that see service where some factor limits the use of other materials. A very common example is the use of special ferritic grades or duplex grades of stainless steels as heat-exchanger tubes where austenitic stainless steels are subject to pitting or chloride SCC from cooling waters. The martensitic grades of stainless steel are used where high strength is required, especially at elevated temperatures, as in compressor rotors.

Cast Stainless Steels. The equivalent cast version of types 304 (S30400) and 304L (S30403) are CF-8 (J92600) and CF-3 (J92500), respectively, and they exhibit approximately the same corrosion response as the wrought alloys. However, castings can have surface layers containing more than the maximum allowable carbon content of 0.08%, which can significantly reduce corrosion resistance of the surface.

In the cast form, the difference between CF-8 or CF-3 and the corresponding molybdenum-bearing grades CF-8M (J92900) and CF-3M (J92800) is insignificant. The CF-3 or CF-8 cast steels are not particularly common, and manufacturers of cast pumps and valves tend to standardize on CF-8M, which has a broader range of applications. The molybdenum grade castings are often more available and less expensive than the 304 or 304L wrought grade equivalents. Since the cast version of these alloys is unlikely to be welded, there is rarely a justification for specifying the low-carbon (L) grades in this case. This assumes that the valves or pumps, if weld repaired by the manufacturer, are properly reheated (solution annealed) to restore optimum corrosion resistance. Availability and price are likely to favor the non-L grade, and properly heat treated castings in CF-8 or CF-8M are likely to be as corrosion resistant as their low-carbon cast or wrought equivalents.

Alloys for Use at Elevated Temperatures

Many of the operations in NH_3 production take place at elevated temperatures. Some of the materials used for these applications are conventional iron-base alloys that have been discussed previously or nickel-base alloys. However, specialized elevated-temperature duties in NH_3 production, petroleum refining, and so forth, have generated a demand for ever better materials specific to these duties. Many of the materials used here are proprietary and have been developed to have high strength and good creep-resistant properties in aggressive, gaseous environments.

The standard stainless steels—types 304, 310, and 347—were commonly used but often failed by cracking at elevated temperatures. A better alloy, HK-40 (J94204, 25Cr-20Ni), was developed, and this became the industry standard (Ref 21).

A later material development produced the HP (N08705, 26Cr-35Ni) alloy with 26% Cr and 35% Ni, which was modified by the addition of alloy elements such as molybdenum, niobium, or tungsten. These modified alloys have improved creep resistance, but still possess good ductility and weldability. Various HP-modified alloys are used in NH₃ applications, one of the most common being HP-45Nb (Ref 22). A more recent development is the production of microalloyed HP alloys in which trace quantities of titanium, zirconium, and rare earths are added during casting. These alloys have better resistance to carburization and better high-temperature creep-rupture properties (Ref 21).

There are new alloys, many of them proprietary such as 25Cr-35Ni-15Co-5W, 28Cr-48Ni-5W, and 35Cr-45Ni plus additional elements, and these offer higher strength and good high-temperature properties (Ref 22).

There has also been some development of coatings to resist high-temperature attack by NH₃. Uncoated type 304 (S30400) and 316 (S31600) and the same steels coated with silica applied by a sol-gel procedure were tested in anhydrous NH₃ at high temperature. The uncoated samples were attacked and formed a nitride scale that embrittled the metal. After 115 h of testing at 500 °C (932 °F) uncoated samples were completely degraded, while the coated samples were only lightly attacked. Multilayer coatings were most effective, and the stainless steel substrates were not sensitized to intergranular attack by the high-temperature coating process (Ref 23).

Metal Dusting

The phenomenon of metal dusting occurs during high-temperature operation, for example,

in steam superheaters downstream of the secondary reformer. It is related to the process of carburization in which carbon migrates into the structure forming hard carbides. Carburization occurs above about 800 °C (1470 °F) in the presence of hydrocarbons that crack to provide the carbon.

Metal dusting occurs at 500 to 800 °C (930 to 1470 °F) on iron-nickel or iron-cobalt alloys in gases containing carbon monoxide. Carbon formation is catalyzed by iron, nickel, or cobalt, and the effect is to produce a surface dust layer consisting of a mixture of metal, oxides, and carbon. This dusting is usually observed as pitting or general corrosion attack. Theoretically, alloys that form protective films of the oxides of chromium, silicon, or aluminum should be more resistant. Virtually all high-temperature alloys can be prone to this attack, but higher steam/CO levels help as does coating with aluminum. In nickel-base alloys such as 601, 601H, 625, and so forth, the attack is tolerable in normal operation (Ref 1).

Hydrogen sulfide in the gas offers some protection from metal dusting since the adsorbed sulfur blocks the surface for the adsorption of CO or CH₄ and other hydrocarbons, and the molecules cannot adsorb and dissociate if their adsorption sites are occupied by sulfur. Similarly, dense oxide scales can prevent ingress of carbon into the structure. If sulfur cannot be tolerated in the process, nickel alloys with high chromium and aluminum or silicon additions are the best materials to resist metal dusting (Ref 24).

Alloy resistance to metal dusting is dependent on its ability to form a protective chromium oxide scale and can be ranked according to its chromium equivalence:

$$\text{Cr equivalent} = \text{Cr}\% + 3 \times (\text{Si}\% + \text{Al}\%)$$

Values of Cr equivalent for alloys (some of which are proprietary) commonly used in high-temperature applications in ammonia plants are shown in Table 3 (Ref 22).

There are also nickel alloys that are said to have exceptional resistance to metal dusting and

elevated-temperature corrosion. The standard alloys such as alloy 600 and alloy 601 have been used in these environments, but other alloys have been developed with superior high-temperature behavior. Alloy 693 (N06693) was tested for a year in CO and 20% hydrogen at 621 °C (1150 °F). Pit depths measured on this alloy were only 0.031 mm (1.2 mils). Pit depths for other alloys tested under the same conditions were (Ref 25):

Alloy	Pit depth	
	mm	mils
800 (N08800)	8.164	321
DS	3.451	136
601 (N06601)	0.033	1.3
620	0.34	13.4
690 (N06690)	0.293	11.5

An example of the failure of alloy 601 occurred in a heat exchanger on an NH₃ plant after only 2½ years service. This failure was found to be caused by contamination of the process side by steam. This caused mineral deposition that destroyed the protective film within about 6 months after the steam ingress into the process side (Ref 26).

Another nickel alloy developed for resistance to metal dusting and carburizing is alloy 602CA (N06025). The metal wastage rate of this alloy is compared with other nickel alloys in a strongly carburizing CO-H₂-H₂O gas in Fig. 2 (Ref 27). This alloy has been tested in an NH₃ plant in Europe and showed no metal dusting at temperatures of 450 to 850 °C (840 to 1560 °F). Alloy 601 had some attack, and alloy 800H was severely attacked.

There are also coatings being developed to resist metal dusting. Diffusion coatings based on oxide formers such as silicon, titanium, chromium, and aluminum have been tested and found to show good potential to extend the lifetime of iron-base and nickel-base alloys under metal dusting conditions (Ref 28).

Nickel and Nickel Alloys

Nickel alloys are seldom used in NH₃ service except at elevated temperatures. They are very

resistant to dry NH_3 , but can be attacked by gaseous NH_3 if more than about 1% water is present. They are resistant to anhydrous NH_3 and exhibit good resistance to nitriding (Ref 29).

Data in Table 4 show the effect of temperature on nitrogen absorption and nitriding depth for nickel alloys compared with a type 310 stainless steel (Ref 30). Samples were exposed to pure NH_3 for 168 h.

Nickel alloy 200 (N02200) will resist NH_4OH only up to about 1% concentration. Dissolved oxygen (DO) may maintain passivation up to about 10% concentration. Higher concentrations

are highly corrosive to nickel even in the presence of air (Ref 31).

The corrosion rate of alloy 200 in agitated solutions of various strengths of NH_4OH at room temperature is shown in Table 5 (Ref 31). These data show that even with agitation nickel is attacked by moderate concentrations of NH_4OH at room temperature.

Alloy 400, with about 30% Cu content, is more resistant than alloy 200 as shown in Table 6 (Ref 31). In solutions of $>3\%$ NH_4OH the corrosion rate is increased considerably by aeration and agitation.

Source: Ref 31

Fig. 3 Corrosion of various copper alloys in (a) deaerated and (b) aerated NH_3 . A carbon steel (A-285) is included for comparison. Source: Ref 33

The corrosion rate of alloy 800 in 5% and 10% NH_4OH at 80 °C (176 °F) was <0.003 mm/yr (0.12 mil/yr) in 7 day laboratory tests (Ref 32).

The Ni-Cr-Mo alloys such as alloy 625 (N06625) and alloy C-276 (N10276) are resistant but find no application because of the adequate resistance of lesser alloys.

Copper and Its Alloys

Copper alloys are generally to be avoided in NH_3 service. Although resistant to pure, dry NH_3 , contamination by water and oxygen will cause SCC and general corrosion. Corrosion of various alloys in deaerated NH_3 are shown in Fig. 3(a) and are compared with the behavior of the same alloys in aerated ammonia in Fig. 3(b) (Ref 33). These data clearly show the corrosive effect of the presence of air in the solution. Carbon steel (A-285) is included in these data for comparison, and its corrosion behavior is also adversely affected by the presence of oxygen at lower oxygen levels.

Ammonia and copper typically react to form an intensely blue copper/ammonium complex. All copper-base alloys can be made to crack in NH_3 vapor, NH_3 solutions, ammonium ion solutions, and environments in which NH_3 is formed. It is generally true that any metal with a small grain size is more resistant to SCC, irrespective of whether the cracking is transgranular or intergranular. The effect of grain size on the time to cracking of yellow brass (C26800) in NH_3 is shown in Fig. 4 (Ref 34).

While some copper-base alloys are far superior to others in their resistance, and dry anaerobic NH_3 does not cause corrosion, it is general industry practice to avoid all use of copper-base alloys in NH_3 and related services. It can be noted in passing that copper in solid solution in ferrous metals (generally less than 3%) added to attain certain physical, mechanical, or corrosion properties does not pose a problem in NH_3 applications.

Copper alloys C11200 and C26000 were penetrated at a rate of 5 $\mu\text{m}/\text{yr}$ (0.2 mil/yr) in anhydrous NH_3 at atmospheric temperature and pressure. Corrosion rates were also low if small amounts of water were present, but oxygen was also probably excluded (Ref 4).

Fig. 4 The effect of grain size on the time to fracture of yellow brass (C26800) in NH_3 . Source: Ref 34

Copper alloy tubes in utility condensers have often been attacked by NH_3 on the steam side. The NH_3 in this case comes from decomposition of amines or hydrazine added to the boiler feed to control oxygen and passivate the boiler surface. Admiralty brass is commonly used to tube such condensers and has been subject to this attack by NH_3 . Copper alloy condensers form a surface layer of cuprous oxide when placed in service. If excess oxygen is present, this oxide layer is converted to cupric oxide, which is readily complexed by NH_3 . Attack by NH_3 in this type of utility condenser is accelerated by air in-leakage. In cases where boiler chemistry cannot be altered or controlled to avoid NH_3 formation, a more resistant alloy, such as copper-nickel, is used (Ref 35, 36).

All copper-base alloys are attacked by NH_4OH unless air is rigorously excluded, which is not feasible in plant practice. The deep royal blue of the copper/ammonium complex is immediately obvious.

Dealloying can occur also in some copper alloys in NH_3 solutions. It was found that dezincification occurred in 70Cu-30Zn brass in 10 N NH_4OH solution at 32 °C (90 °F). Corrosion and dezincification were increased by increasing stress applied to the alloy. The mechanism of this increased attack was shown to be due to an increase in open circuit potential and a shift in the polarization curve under the influence of applied stress (Ref 37).

Titanium and Titanium Alloys

Titanium is not attacked by atmospheres containing NH_3 , but can be corroded at elevated temperatures. The protective oxide film is effective in NH_3 up to at least 300 °C (570 °F) (Ref 4). At higher temperatures, NH_3 will decompose into nitrogen and hydrogen that may cause hydrogen embrittlement of titanium. Titanium corroded at 11.2 mm/yr (440 mils/yr) in an NH_3 -steam mixture at 221 °C (430 °F). This high corrosion rate was thought to be associated with hydriding. Titanium shows excellent resistance to corrosion in up to 70% NH_4OH up to the boiling point (Ref 38). The corrosion rate of titanium in 100% anhydrous NH_3 is <0.13 mm/yr (5 mils/yr) at 40 °C (105 °F). In 28% NH_4OH solution at room temperature, the rate is 0.0025 mm/yr (~0.1 mil/yr) (Ref 39).

Zirconium and Its Alloys

Zirconium is resistant to NH_3 even at elevated temperatures. The corrosion rate of zirconium Zr702 (R60702) in wet NH_3 at 38 °C (100 °F) is less than <0.127 mm/yr (<5 mils/yr) and in 28% NH_4OH at up to 100 °C (212 °F) is <0.025 mm/yr (<1 mil/yr) (Ref 40). Zirconium is stable in NH_3 up to about 1000 °C (1830 °F) (Ref 4).

Niobium and Tantalum

Niobium is not attacked by 13% and 25% NH_4OH solutions at 20 to 100 °C (68 to 212 °F) (Ref 3).

Tantalum is resistant to anhydrous liquid NH_3 , but should not be exposed to the gaseous mixtures encountered in NH_3 synthesis at elevated temperature. Above about 250 °C (480 °F), it reacts rapidly with hydrogen to form brittle hydrides. Tantalum is not corroded by 10% aqueous NH_4OH solutions up to 100 °C (212 °F), but is attacked by hot, concentrated NH_4OH solutions (Ref 3).

Other Metals and Alloys

Lead is resistant in NH_3 at temperatures up to 60 °C (140 °F) and hard lead (alloyed with antimony) is satisfactory up to 100 °C (212 °F) in dry NH_3 . Lead is also resistant to NH_4OH at room temperature (Ref 41). The corrosion rate is very sensitive to the presence of air and agitation. In 27% NH_3 solution at 20 °C (68 °F), lead had a corrosion rate of 110 g/m²/d (3.3 mm/yr) with rapid agitation and only 21 g/m²/d (0.63 mm/yr) without agitation (Ref 7).

Tin is resistant to dry NH_3 and saturated NH_3 solutions, but dilute NH_3 solutions corrode tin.

Zinc is not resistant to NH_4OH .

Magnesium is not attacked by wet or dry NH_3 at ordinary temperatures, but attack may occur if water vapor is present.

The precious metals are also not used. In fact, there is a potential hazard if silver is exposed under some conditions because explosive azides may be formed. Precious metals are not employed, and silver or silver-rich alloys are not to be employed in NH_3 or NH_4OH .

Nonmetallic Materials

Although ferrous and nonferrous alloys are the most commonly used materials for the manufacture, handling, and storage of NH_3 and NH_4OH , nonmetallic materials are also used for some applications. These include:

- Elastomers
- Plastics, both thermoplastics and thermosetting resins

- Carbon and graphite
- Glass

Elastomers. Some elastomeric materials are attacked by NH_3 , for example, butyl, Viton A (E.I. Du Pont Co.), hard rubber, isoprene, and natural rubber. Satisfactory materials include Chemraz (Greene, Tweed), Kalrez (E.I. Du Pont Co.), chloroprene rubber, acrylonitrile rubber (Buna N), and butadiene-styrene rubber (Buna S). Ethylene-propylene-(diene) rubber (EPDM) is resistant to NH_3 , but may be attacked by oils present in compressed gas systems. Buna N elastomer used in pumps is rated as suitable for cold NH_3 gas but fair to poor in hot gas. Neoprene is suitable in cold NH_3 while polytetrafluoroethylene (PTFE) is suitable in cold or hot NH_3 (Ref 42).

Satisfactory materials in NH_4OH include Chemraz, Kalrez, and chloroprene rubber. Some elastomers that are attacked and are unsatisfactory are butyl, Viton A, hard rubber, isoprene, and natural rubber.

Temperature limits for various elastomers are given in Table 7. These data are a compilation from various sources.

Plastics. Most plastics are chemically resistant to NH_3 and NH_4OH at ambient temperatures. However, due to the hazardous nature of NH_3 , the use of plastics is generally not recommended except in seals and gaskets, where fluoropolymers are typically used.

Thermoplastics. Resistant grades of fluoropolymers are ethylene chlorotrifluoroethylene (ECTFE), for example, Halar (Allied Corp.), ethylene trifluoroethylene (ETFE), for example, Tefzel (E.I. Du Pont Co.), polyvinylidene fluoride (PVDF), for example, Kynar (Arkema), fluorinated ethylene propylene (FEP), perfluoroalkoxy (PFA), and polytetrafluoroethylene (PTFE). Some plastics that are generally unsatisfactory in NH_3 are acrylonitrile-butadiene-styrene (ABS), epoxy, certain polyesters, polyisobutylene, and polystyrene. Data on temperature limits for various common thermoplastics are shown in Table 8. These data are a compilation from various sources. Various manufacturers list elevated-temperature limits for plastics in liquid NH_3 , and these are included in this table. They are not, however, of very practical interest since it is highly unlikely that plastics would be used in elevated-temperature (therefore, also high-pressure) liquid NH_3 . In the unlikely event that an application for a plastic

NR, not resistant. Hypalon and Viton are registered trademarks of E.I. Du Pont Co.

was being considered in liquid NH_3 , the subzero properties would be more relevant and should be investigated.

One area of interest is the difference in behavior of polyvinyl chloride (PVC) and chlorinated polyvinyl chloride (CPVC). In many environments CPVC is more resistant than PVC and can

withstand higher temperatures. This is not the case, however, in NH_3 and amines. Polyvinyl chloride has generally good resistance to NH_3 and some amines, even at somewhat elevated temperatures, while CPVC has extremely poor resistance to NH_3 or NH_4OH , and limited resistance to most amines, even at ambient

temperatures. This is due to the extremely high reactivity of amines and chlorine, the higher availability of chlorine in CPVC, and the lower bond strength of CPVC versus PVC. Even at fairly low concentrations and temperatures, NH_3 and many amines are capable of rapid dehydrochlorination of CPVC. One CPVC pipe handling 28% NH_4OH at ambient temperature failed after only 1 year in service (Ref 43).

If polyethylene is used to store concentrated aqueous ammonium solutions, there is a weight loss due to outward diffusion through the plastic. A solution of 27% NH_4OH solution kept in a 500 mL bottle (1 mm (0.04 in.) wall thickness) at 20 °C (68 °F) for 54 days lost 3.6% of its weight (Ref 3).

Use of many of these thermoplastics is confined to linings for pipe and vessels, rather than as solid construction items, because of the hazardous nature of NH_3 . Recommended temperature limits for plastic-lined steel pipes are given in Table 9 (Ref 44).

Thermoplastics are also used as the resistant liner in dual-laminate construction in which fiber-reinforced plastic (FRP) is used as the reinforcing, structural element. The corrosion resistance depends on the resistance of the thermoplastic liner, although resistant resins are often used in the FRP reinforcement in case of permeation and leaks in the thermoplastic liner. Most common thermoplastics are used in this type of construction, and many of them are suitable for use in NH_3 applications. Data on temperature limits for various thermoplastics used for dual-laminate construction for NH_3 service are given in Table 10 (Ref 45).

Thermosetting Resins. The fiberglass-reinforced thermosetting composites, commonly called FRPs, have a resistance determined by the polymer used. Some suggested concentration and temperature limitations of FRP are shown in Table 11. Data are a compilation from various sources.

Carbon and graphite are resistant to NH_4OH . However, with impervious graphite heat exchangers, an epoxy resin should be specified rather than phenolic, which is attacked by alkaline chemicals. Carbon and graphite are resistant to all solutions of NH_3 up to their limiting temperature, which depends on the individual grade and formulation. Graphite is resistant to anhydrous NH_3 over the full range of concentration up to the temperature limit of the graphite. Fluorocarbon-bonded graphite, Diabon F100 (SEL Carbon Group), is resistant in 20% NH_3 /caustic NH_3 at up to 40 °C (105 °F) (Ref 46).

Glass is resistant to about 60 °C (140 °F) in very dilute solutions of NH_4OH (perhaps 1%), but will withstand solutions to pH 14 at room temperature in lined steel (Ref 47).

Corrosion by Phosphoric Acid

Ralph (Bud) W. Ross, Jr., Consultant

PHOSPHORIC ACID (H_3PO_4) is a major industrial chemical. It follows sulfuric and nitric acids in importance and tonnage produced. Phosphoric acid is made from phosphate rock by two methods: the wet process and electric furnace. Phosphoric acid is not a particularly strong acid. It is a stronger acid than acetic acid but weaker than sulfuric acid and hydrochloric acid. Phosphoric acid is incompatible with strong caustics and readily reacts with metals to form flammable hydrogen gas. Synonyms for phosphoric acid are orthophosphoric acid, metaphosphoric acid, and white phosphoric acid. Industrial or merchant grades include superphosphoric, defluorinated, and technical-grade phosphoric acid. Food-grade phosphoric acid is primarily produced by the electric furnace method to eliminate impurities in the acid.

Phosphoric acid is less corrosive than sulfuric and hydrochloric acids. Pure phosphoric acid has no effective oxidizing power and is classified as a nonoxidizing acid, much like dilute sulfuric acid. Commercial phosphoric acid made by wet process/acid digestion of phosphate rock usually contains impurities such as fluorides, sulfates, fluorosilicic acid, metal ions, and chlorides that markedly increase its corrosivity. Oxidizing compounds such as ferric salts may also be present to influence corrosion.

Phosphoric acid is used in nearly every major industry. In the chemical industry, it is used in the manufacture of phosphates and as a catalyst for other chemical reactions, such as ethanol production. The electronics industry uses H_3PO_4 in the preparation of semiconductors and printed circuit boards. Pure H_3PO_4 is used in the food industry as an acidulant in cola-type beverages and in jams and jellies. Combined with ammonia, it produces nutrients for yeast production. It is also used in sugar refining and production of pet foods. In water treatment, H_3PO_4 is used to remove mineral deposits from process equipment and boilers. It acts as a binder for aluminum refractories. In metal processing, H_3PO_4 is the main ingredient in phosphating solutions for ferrous metals. It is used to clean aluminum in bright dip baths. Phosphoric acid is also used as a nutrient for biological processes in secondary wastewater treatment plants. Its major use is in the agriculture industry, where it is used to produce fertilizer solutions and as a mineral

supplement in cattle feed. Other uses are the production of pharmaceuticals, flame retardants, electrolytic fuel cells, cement processing, tanning of leather, firebrick and silica brick, crucibles and molds, toilet preparations, varnish, and synthetic rubber.

Corrosion of Metal Alloys in H_3PO_4

A survey of metal groups reveals a range of suitability for use in the manufacture, transport, and handling of H_3PO_4 .

Aluminum shows no useful corrosion resistance in pure phosphoric acid. It is not used in the manufacturing or handling of phosphoric acid because of its high corrosion rates and the evolution of dangerous hydrogen gas from these reactions.

Carbon Steel and Cast Irons. Wrought and cast carbon and low-alloy steels show very high rates of corrosion in all concentrations of phosphoric acid, even at room temperature, and are not used in this service. Gray cast irons and nickel cast irons are not suitable, but high-silicon iron ($\approx 14\%$ Si), although brittle, shows good to excellent resistance in all concentrations of pure phosphoric acid, although there is measurable attack above 100°C (212°F). However, they do not resist acid contaminated with fluorides.

Stainless Steels. The utility of stainless steels in phosphoric acid varies with the particular family of alloys and improves with higher alloy content. The 11 to 13% Cr martensitic grades and related low-chromium ferritic grades, such as types 405 (UNS S40500) and 409 (UNS S40900), find no application in this service.

Ferritic Stainless Steels. The 17% Cr stainless steels, such as the prototypical 430 (UNS S43000), show very high rates of corrosion in phosphoric acid in all concentrations at room temperature. The extralow-interstitial-grade 26-1 (UNS S44626) ferritic stainless steel shows active/passive behavior, as does 29-4-2 (UNS S44800). Preliminary corrosion testing by the Tennessee Valley Authority Fertilizer Division has shown 29-4-2 to have acceptable corrosion resistance in some phosphoric acid solutions. More corrosion data are needed for these modern ferritic stainless steels before they can be used in such service. Also, because of high nil ductility

transition temperatures, their use is usually limited to thin-walled equipment such as heat-exchanger tubes.

Austenitic Stainless Steels. Conventional stainless steels are the prime materials for phosphoric acid service.

Type 304L (UNS S30403) stainless steel has been used in some phosphoric acid solutions, because it has good general corrosion resistance up to 80% acid below 74°C (165°F). Because the alloy is subject to stress-corrosion cracking in the presence of chlorides and is very susceptible to pitting and crevice corrosion from contamination by chlorides or fluorides, very little is used for handling, storage, or manufacturing of H_3PO_4 . In the active state, it will be rapidly corroded by phosphoric acid, with the release of hydrogen gas (Table 1) (Ref 1) that may produce flammable and explosive hydrogen/air mixtures.

For comparison, at 196 ppm Cl^- , type 316 (UNS S31600) corrosion rate is 0.03 mm/yr (1 mil/yr). Type 316L stainless steel is the preferred material in the phosphoric acid industry for acid storage, handling, and transport (Ref 2). It has excellent corrosion resistance: less than 0.25 mm/yr (10 mils/yr) from <1 to 60% phosphoric acid (44% P_2O_5) up to the boiling point. From 60% (44% P_2O_5) to approximately 90% acid (66% P_2O_5), 316L has good resistance up to approximately 115°C (240°F). In superphosphoric acid (typically, 69% P_2O_5), 316L has excellent resistance at even higher temperatures, 120 to 185°C (250 to 365°F). The isocorrosion chart for 316L in phosphoric acid is shown in Fig. 1 (Ref 1).

Table 1 Effect of chloride on corrosion of type 304 stainless steel in 75% phosphoric acid

Chlorides, ppm	Corrosion rate	
	mm/yr	mils/yr
8	0.04	1.4
15	0.28	11.0
23	12.9(a)	508(a)
39	23.1(a)	910(a)
117	24.7(a)	973(a)
196	27.5(a)	1081(a)

Temperature was 29.4 to 37.8°C (85 to 100°F) for 23 h. (a) Hydrogen gas evolved, and acid turned green.

Type 316L and most of the austenitic stainless steels are very susceptible to the effects of increasing temperature and acid concentration. Maximum corrosion of 316 stainless steel occurs at 79 to 91% acid concentration (Fig. 2) (Ref 3).

Type 317L (UNS S31703) stainless steel behaves similarly to 316L and can be used interchangeably up to approximately 60% acid. At this point, 316L apparently exhibits better corrosion resistance than 317L in pure acid (Fig. 1) (Ref 1, 4). Note the significantly better performance of 316L than 317L between 60 and 100% H_3PO_4 (44 and 73% P_2O_5). Above 105% H_3PO_4 (76% P_2O_5), the two stainless steels show similar corrosion resistance.

Modern duplex (austenitic/ferritic) stainless steels are exemplified by alloys 255 (UNS S32550) and 2205 (UNS S31803). Figure 1 also presents corrosion data for the duplex alloy 255.

Surprisingly, this duplex exhibits corrosion resistance similar to 317L but inferior to 316L. This relationship would probably change in contaminated phosphoric acid, where chlorides and fluorides result in accelerated corrosion of 316 stainless steel and may attack the ferrite phase in duplex grades. Duplex alloy 2205 has been introduced in Europe as a practical material for marine cargo applications, having been installed in 14 cargo ships since 1987 (Ref 5).

Figure 3 compares the corrosion resistance of 316, 317, and cast alloy 20 (UNS N08007) in 105% super-phosphoric acid (76% P_2O_5) (Ref 6). Note that all of the alloys show less than 0.25 mm/yr (10 mils/yr) corrosion rate between 90 and 150 °C (195 and 300 °F).

Superaustenitic Stainless Steels. The alloy 20Cb-3 (UNS N08020), 20Mo-4 (UNS N08024), and 20Mo-6 (UNS N08026) stainless steels show

no better corrosion resistance than type 316L up to approximately 60% pure phosphoric acid (44% P_2O_5) at boiling temperatures (Fig. 4) (Ref 7). Between 70 and 90% acid, alloy 27-7MO (UNS S31277) shows improved corrosion resistance over 316L, 317L, and alloy 825 (UNS N08825) below the boiling point (Fig. 5) (Ref 8, 9). At higher concentrations and temperatures, these alloys would have very high corrosion rates. The 6 to 7% Mo superaustenitic stainless steels, alloys AL-6X (UNS N08366), AL-6XN (UNS N08367), 254 SMO (UNS S31254), 654 SMO (UNS S32654), 1925hMo (UNS N08926), 20Mo-6 (UNS N08026), and 27-7MO (UNS S31277), may also be useful in contaminated phosphoric acid because of their higher molybdenum content. These alloys are usually referred to as 6% Mo alloys.

Alloys 28 (UNS N08028), also known as 3127LC, UR SB8, and alloy 31 (UNS N08031), are similar in composition and have the highest phosphoric acid corrosion resistance of the superaustenitic stainless steel grades because of their increased chromium and molybdenum content. These alloys can be used in pure phosphoric acid up to 80% acid (58% P_2O_5) to the boiling point (Fig. 5) (Ref 4). Their corrosion resistance falls as acid concentration increases

Fig. 2 Effect of acid concentration on corrosion rate of type 316L stainless steel in phosphoric acid at 163 °C (325 °F)

Fig. 3 Corrosion behavior of various stainless steels in 105% superphosphoric acid

Fig. 4 Corrosion of alloy 20 stainless steels in boiling phosphoric acid

from 80 to 90%. The corrosion resistance of these alloys is quite good up to 260 °C (500 °F) at 110% acid concentration.

Pure superphosphoric acid is highly corrosive toward both stainless steels and nickel-base alloys at 200 °C (390 °F). However, its corrosiveness declines when it is combined with various metallic ions. Magnesium has been shown to be very effective in reducing corrosion of these alloys in hot superphosphoric acid (Ref 10). The test results have shown that an addition of approximately 0.25% Mg^{2+} can drastically reduce corrosion rates in hot superphosphoric acid containing minor contaminants. Magnesium salts inhibit corrosion by forming a protective layer on the surface of the metal. Magnesium occurs naturally in many phosphates and can be added to the acid in order to reduce corrosion.

Alloy 825 (UNS N08825) is quite similar to alloy 20Cb-3 and is sometimes employed in contaminated acid.

Nickel-Rich G-Type Alloys. A family of chromium-bearing nickel-rich alloys has been developed specifically for wet-process phosphoric acid service where chloride and fluoride contamination is present. The prototype was alloy F (UNS N06001) with a nominal composition of 22Cr-45Ni-22Fe-6Mo-Cb,Si,W. This alloy evolved into superior grades based on alloy G (UNS N06007).

The modern G-type alloys, G-3 (UNS N06985), G-30 (UNS N06030), and G-35 (UNS N06035), show excellent corrosion resistance in wet-process phosphoric acid (Ref 11). However, they are not cost-effective in pure phosphoric acid contrasted to the less expensive, conventional types 316L and 317L. They would show resistance comparable to alloy 28 in pure phosphoric acid. The order of resistance between the G-type alloys and alloy 28 (UNS N08028) appears to vary with the specific phosphate ore processed, which is to say that the kind and concentration of contaminants vary in an unpredictable manner in various geographic locations. Alloy G-35 showed somewhat better corrosion resistance than alloys G-30 or 31 (UNS N08031) in wet-process phosphoric acid at 121 °C (250 °F), which suggests the alloy may

offer better performance in evaporator tubing applications (Fig. 6) (Ref 12).

Copper and copper alloys have been used in the past in heat exchangers for phosphoric acid. However, the corrosion rates of the copper alloys are generally very high in phosphoric acid, due to aeration and oxidizing contaminants in the acid. Copper alloys display high corrosion rates, greater than 1.27 mm/yr (50 mils/yr) in phosphoric acid from 5 to 90% (4 to 65% P_2O_5) at 25 °C (75 °F), depending largely on the presence of oxidizing species in the acid. Higher temperatures cause very significant increases in corrosion rates (Ref 13).

Contamination of phosphoric acid containing sulfate, sulfite, chloride, and fluoride ions by dissolved oxygen (DO) can rapidly increase the corrosion rate of copper alloys (as high as 150 times the rates reported previously). Ferric ions cause accelerated corrosion even in the absence of DO. This limits the usefulness of copper alloys in phosphoric acid service. Generally, copper and copper alloys will form voluminous and porous films and scales that result in pitting underneath. There is little evidence of the use of copper and copper alloys in phosphoric acid service in the published literature.

Nickel Alloys. The nickel-base (>50% Ni) alloys comprise two groups: with and without chromium additions. Only the second group demonstrates significant passivation effects.

Chromium-Free Alloys. Pure nickel alloys, such as alloys 200 (UNS N02200) and 201 (UNS N02201), have no practical applications in phosphoric acid. High rates of corrosion, between 0.51 and 1.27 mm/yr (20 and 50 mils/yr), can be experienced, especially in aerated solutions or solutions containing oxidizing ions (e.g., Fe^{3+} , Cu^{2+}). Also, the 68%Ni-32%Cu alloy 400 (UNS N04400) is not generally used in phosphoric acid service. Alloy 400 does exhibit excellent corrosion resistance in deaerated phosphoric acid, with corrosion rates of less than 0.05 mm/yr (2 mils/yr) between 10 and 100% acid up to 80 °C (175 °F) (Ref 14).

The nickel-molybdenum alloy B-2 (UNS N10665) contains 28% Mo. It shows excellent corrosion resistance up to 50% acid up to 175 °C

(350 °F). Both wrought and cast versions of alloy B-2 are available for pump and valve components. Because of its 28% Mo content, it is quite an expensive nickel-base alloy. It is also subject to accelerated corrosion when oxidizing ions (e.g., Fe^{3+} , Cu^{2+} , etc.) are added to the acid, and it has little to offer in phosphoric acid service.

Chromium-Bearing Alloys. The basic nickel-chromium alloy 600 (UNS N06600) is of limited use in phosphoric acid and is not generally used. In Fig. 5, a wide range of conditions for use of alloy 825 is shown. Alloy 625 (UNS N06625) and the C-family of alloys are more expensive materials available for pure phosphoric acid service, but they are not more resistant than alloy 825 (Ref 14). Consequently, they are used infrequently. The C-family includes C-4 (UNS N06455), C-276 (UNS N10276), C-22 (UNS N06022), C-2000 (UNS N06200), 59 (UNS N06059), and 686 (UNS N06686). They are similar in composition and corrosion characteristics and may also be useful in contaminated phosphoric acid because of their higher molybdenum content. These alloys also exhibit active/passive behavior near the boiling point and should not be used under these conditions. In fact, the Ni-Cr-Mo grades often show less resistance than alloy G-30 (UNS N06985) under wet-process conditions.

Lead shows excellent resistance to pure phosphoric acid up to 85% acid (58% P_2O_5) to 95 °C (205 °F) and reasonably good resistance to 207 °C (405 °F). The corrosion rates in the latter case are 0.51 to 1.27 mm/yr (20 to 50 mils/yr) under static conditions. Lead-lined vessels have been used in the past in the manufacture and storage of phosphoric acid. Lead is significantly affected by velocity conditions, because the protective phosphate film is easily removed. Because of environmental and health concerns, lead has no use in today's modern production and handling of phosphoric acid.

Titanium Alloys. Titanium grade 2 (UNS R50400) shows good corrosion resistance to aerated pure solutions of phosphoric acid up to 30% (22% P_2O_5) at room temperature (Fig. 7) (Ref 15). Titanium grade 12 (UNS R53400)

Fig. 5 Isocorrosion diagram for alloy 28 and various nickel alloys in phosphoric acid

Fig. 6 Corrosion of alloys G-35, G-30, and 31 in wet-process phosphoric acid at 121 °C (250 °F)

offers no particular advantage. Increasing phosphoric acid concentration and/or temperature causes a rapid decrease in corrosion resistance of titanium. Titanium grades 7 (UNS R52400) and 11 (UNS R52250) offer better resistance than pure titanium by virtue of their palladium additions. Contamination of phosphoric acid with free fluoride ion would also accelerate corrosion of titanium alloys. Because of costs and marginal corrosion resistance, titanium alloys are not used in phosphoric acid service.

Zirconium alloys resist attack in phosphoric acid at concentrations up to 55% (40% P_2O_5) and temperatures exceeding the boiling point. Corrosion rates of zirconium alloys increase rapidly, as the temperature increases, for concentrations above 55% acid. Unalloyed zirconium (UNS R60702) and its alloys with tin and niobium, respectively (UNS R60704, UNS R60705), resist dilute phosphoric acid solutions at elevated temperatures, as shown in Table 2 (Ref 16).

Zirconium alloys exhibit better corrosion resistance to boiling phosphoric acid solutions than titanium alloys (Fig. 8). Fluorides, even at very low impurity levels, will attack zirconium. Because of costs and marginal corrosion resistance, zirconium alloys are not used in phosphoric acid service.

Precious Metals. The only metals that are corrosion resistant to pure phosphoric acid for all concentrations and temperatures are gold,

platinum, platinum plus iridium, and platinum-rhodium. Silver was found to be satisfactory for all concentrations up to approximately 185 °C (365 °F).

Corrosion of Metals in Phosphoric Acid Vapors. As shown in Table 3, only the most corrosion-resistant alloys showed acceptable resistance to phosphoric acid vapors: alloys 20Cb-3, 825, G, G-3, and B-2 (Ref 17). The newer nickel-rich, highly-alloyed stainless steels (alloy 28) and other nickel-base alloys (625, C-276, G-30) would be expected to show acceptable resistance in phosphoric acid vapors, although there is no other information available.

Resistance of Nonmetallic Materials

Nonmetallic materials may be chemically attacked in some corrosive environments, which can result in swelling, hardening, or softening phenomena (if the material is a plastic or elastomer); extraction of ingredients; chemical conversion of the nonmetallic constituents (molecular changes); cross-linking oxidation; and/or substitution reactions. The general properties of the nonmetallic can be greatly changed by these chemical reactions. Other environmental effects can adversely affect a non-metallic, such as stress, change in weight, change in volume, and change in mechanical properties.

A change in hardness is very indicative of attack on organic materials. The nonmetallic material can also undergo discoloration.

Quantitative corrosion or environmental degradation data for nonmetallic materials of construction used in phosphoric acid applications are not as extensive as they are for metals. The reason is that nonmetallics do not deteriorate or corrode by the specific forms of corrosion experienced with metals. Therefore, when corrosion tests are conducted on nonmetallics, the data usually show a “go” or “no-go” result.

Rubber and elastomeric materials can be successfully used as sealing components at various temperatures and concentrations of phosphoric acid. Selection of the proper elastomeric material is critical for assuring long-term, reliable service. Although Table 4 contains information on the performance of elastomer families, variations in elastomer compound formulations and cure chemistry can result in performance differences (Ref 18–21). Therefore, testing of elastomeric seals is always recommended before use.

Most standard elastomeric materials are not suggested for use in superphosphoric acid, except chlorbutyl rubber. High-performance fluoroelastomers and perfluoroelastomers should perform well in superphosphoric acid, but testing is advised. Rubber linings are used widely in acid evaporator bodies and may also be used for scrubbers, storage tanks, and so on in the manufacture and transportation of phosphoric acid. Rubber-lined steel pipe, pumps, and valves are also used, as well as gaskets. In conjunction with acid-resistant brick as an outer lining, rubber linings can be used at higher temperatures, up to approximately 115 °C (240 °F) (Ref 19).

Elastomers are combustible materials that may evolve toxic, corrosive, and otherwise dangerous fumes. Extreme caution should be followed when welding or cutting near elastomer sealing components. One should follow industry safety standards and good fire-prevention techniques at all times.

Plastics. Both thermoplastic and thermosetting polymers find application in phosphoric acid under specific conditions.

Table 2 Corrosion of zirconium alloys in phosphoric acid

Acid concentration, %	Temperature		Corrosion, rate					
	°C	°F	Zr702		Zr704		Zr705	
			mm/yr	mils/yr	mm/yr	mils/yr	mm/yr	mils/yr
5–30	25	75	<0.13	<5
5–35	60	140	<0.13	<5
5–50	100	210	<0.13	<5
35–50	25	75	<0.13	<5

Fig. 8 Corrosion behavior of titanium and zirconium alloys in boiling phosphoric acid

Thermoplastics are materials that can be softened or fused when heated, then they rehardened when cooled. Major thermoplastics used today are:

- *Polyolefins*: polyethylene, polypropylene, polybutylene, and polymethylpentene
- *Vinyls*: PVC and CPVC
- *Fluoropolymers*: PTFE, FEP, PFA, CTFE, ECTFE, ETFE, and PVF
- *Crystalline polymers*: nylons, polyesters, acetals, and polyphenylene sulfide
- *Amorphous polymers*: ABS, SAN, polycarbonate, PSO, PES, and PPO.

The unfluorinated thermoplastics generally have strict individual temperature limits that vary from as low as 4.4 to 15.6 °C (40 to 60 °F) to 82 to 107 °C (180 to 224 °F).

Maximum corrosion resistance of the thermoplastics is achieved by replacing hydrogen with chlorine and/or fluorine in the molecular structure of the plastic (fluoroplastic). Thermal resistance and strength are thereby increased, with a useful maximum temperature range of the order of 121 to 260 °C (250 to 500 °F). The fluoroplastics find major applications in liners for pipe, valves, pumps, vessels, tower packing, seals, and packing. The most resistant plastics are fluorinated: PVDF, FEP and PTFE or PFA. The nonfluorinated thermoplastics are generally not used in the manufacture of phosphoric acid but may be used in the storage of the acid.

Plastics, in general, offer good to excellent corrosion resistance in phosphoric acid, ease in fabrication, low cost, smooth surfaces (which results in less scale buildup), absence of corrosion deposits, light weight, and ease of installation. They also provide good thermal insulation, require low tooling costs, are non-conductive, and do not contaminate the acid with metal ions. Their disadvantages are degradation in hot, strong acid solutions; flammability (producing deadly and corrosive fumes); poor mechanical and fatigue strengths at elevated temperatures; a tendency to leak at joints; low temperature limits; and poor abrasion resistance. Quality control during manufacture and fabrication of the plastic components is critical. There may be permeation, absorption, and swelling and leaching problems in some cases, and they may suffer from ultraviolet degradation or delamination. Table 5 presents chemical resistance data on many of the common plastics used in phosphoric acid service (Ref 22, 23).

Thermoset plastics are materials that become permanently rigid when heated or cured. Reinforced thermosetting plastics are produced by combining a fiber (glass, wood, paper, cotton, metal, Kevlar, or carbon) and a resin (polyester, epoxy, furan). In some applications, phenol-formaldehyde resins have been used to approximately 95% acid at 60 °C (140 °F) (Ref 24).

The primary product used in the chemical processing industry is fiberglass-reinforced plastic (FRP), which is used in the handling, storage, and transportation of phosphoric acid solutions because of its excellent corrosion

resistance in a wide variety of acid conditions. The FRP is resistant to all phosphoric acid contaminants at room temperature. It may have a temperature limit of approximately 60 °C (140 °F); however, some suppliers have reported that several resins may be available that will offer higher operating temperatures. Therefore, the manufacturer of the equipment and the resin supplier should be consulted to ensure that the operating temperature and the phosphoric acid

concentration are compatible for the composition of the FRP selected for the application. However, FRP is subject to impact damage. Glass fibers in the FRP will be attacked by fluoride ions in the phosphoric acid or by hot concentrated H₃PO₄ if the outer laminants are damaged, exposing the glass fibers.

Carbon and graphite are chemically identical but have different physical structure and physical properties. They are resistant to all

Table 3 Corrosion of alloys in phosphoric acid vapors

Material (UNS)	Temperature		Corrosion rate	
	°C	°F	mm/yr	mils/yr

concentrations of phosphoric acid up to and including the boiling point and are used extensively in the production of phosphoric acid. Carbon is used primarily in carbon brick and ring packing for towers. Graphite is used in vessels, piping, and pumps.

Graphite is used in fibrous form as gasket material. Impervious graphite is impregnated with organic resins to fill the pores inherent in the original structure. Impervious graphite is used in heat exchangers because of its good heat-transfer rate (equivalent to copper alloys). Impervious graphite is brittle and must be protected from mechanical shock or severe tensile stress, such as by water freezing in exchanger tubes or mechanical abuse during cleaning. The temperature limit is approximately 260 °C (500 °F) (Ref 25).

Ceramic Materials. Many of the ceramic materials, such as glass, stoneware, and acid-resistant brick, can be used in the production and handling of phosphoric acid. Cement and concrete structures are nonresistant, however.

Glass. Borosilicate glass can be used in phosphoric acid in all concentrations up to 95% acid (69% P₂O₅) and 100 °C (212 °F) temperature (Ref 26). Glass is severely limited by fluoride contamination and should not be used in such phosphoric acid solutions. Glass is used for piping, pumps, and flow meters. Very high concentrations of phosphoric acid and temperatures above 100 °C (212 °F) should be avoided because of chemical attack. Glass is also prone to mechanical damage, and appropriate armor or other protective systems should be employed.

Porcelain and stoneware can be used in phosphoric acid up to 95% phosphoric acid (69% P₂O₅) at 60 °C (140 °F) maximum temperature or up to 100 °C (212 °F) at concentrations less than 60%. Stoneware and porcelain can be made into sinks, pipes, valves, pumps, insulators, and acid nozzles. Both materials are subject to mechanical damage and have low tensile strengths.

Acid-resistant brick is used extensively in the manufacture of phosphoric acid. It is common to use membrane linings under acid-resistant brick in tanks and other process vessels to minimize the possibility of corrosion of the steel substrate. Acid-resistant brick-lined steel components have been used in conjunction with lead, rubber, or plastic membranes. Areas subject to acid spillage are also made of acid-resistant brick. The limiting factor in using acid-resistant brick would be the cements and mortars. Manufacturers should be consulted for a particular cement or mortar, especially if fluoride contamination exists in the phosphoric acid.

Because there are some inconsistencies in the published data purporting to indicate where various non-metals can be used safely in

phosphoric acid, it is strongly recommended that either the end user conduct corrosion tests or have previous experience with a particular non-metallic before selecting one for use in the manufacture, transportation, or storage of phosphoric acid. Nearly all of the information supplied previously on nonmetals was given as general guidance only, and very little referred to actual service experience or case histories.

Another problem area with the use of some of the nonmetals is that fabrication of equipment from nonmetals is quite variable in quality. The reason for this is that many of the initial ingredients in the plastic are supplied to others who combine, mix, and formulate the materials before fabricating the final product. Therefore, many processing variables can occur that can lower the mechanical and chemical properties of the nonmetallic. Excellent service with nonmetals can be achieved if qualified component fabricators are selected to manufacture the needed equipment.

Corrosion by Mixed Acids and Salts

Narasi Sridhar, Southwest Research Institute

PROCESS FLUIDS are often found to contain various salts from catalysts, impurities from mixing water, or corrosion products. Therefore, estimating the performance of materials in the chemical process industry (CPI) requires an understanding of the chemistry of these environments and its effects on corrosion. The corrosion rate in many acid or acid-plus-salt mixtures is a complex function of solution and alloy compositions, rendering interpolation of data from pure acids difficult (Ref 1). For example, fluoride acts as an aggressive species in dilute sulfuric acid but as a corrosion inhibitor in concentrated sulfuric acid (Ref 2).

The inability to predict the corrosion behavior of materials in complex CPI streams has considerable economic and safety impacts. Mixtures of acids or acids and salts are of great importance to the CPI for use in digestion of solids, as a promoter in reactions, as a scale remover, and as a complexant, for example. Often, when a pure acid is thought to have been used, minor dissolved species from catalysts or the corrosion of upstream components can complicate materials selection. Corrosion data in pure acids are more readily available than in acid mixtures. However, the corrosion behavior of materials in acid mixtures cannot always be interpolated from a knowledge of their corrosion behavior in individual acids. The object of this article is to assess the performance of Ni-Fe-Cr-Mo alloys in mixed acids and salts in an objective manner. The nominal composition of these alloys is given in Table 1. The table lists a range of commercially available alloys, although a few representative alloys are discussed with respect to their corrosion behavior. However, caution must be used in interpreting the data for materials selection:

- Data are based on short-term immersion tests and may not accurately reproduce plant conditions.
- Weight-loss data are not reliable indicators of the susceptibility or rate of localized corrosion.
- Corrosion phenomena, such as stress-corrosion cracking, galvanic effects, and intergranular corrosion, are not considered.
- Other factors, such as heat transfer, flow effects, presence of minor constituents, vapor-liquid interfaces, galvanic effects,

microstructure (welding, other fabrication), and corrosion test methods, may play a role in corrosion processes.

The information presented should be used as guidance for further process-specific testing. The focus is on Ni-Fe-Cr-Mo-type alloys because these alloys constitute the bulk of the corrosion-resistant alloys used in the CPI, and considerable data are available related to these alloys. Data for other alloys sometimes used in the CPI, such as titanium and zirconium, are presented elsewhere in this Volume.

For the nonoxidizing acids, the corrosion rate (CR) of Ni-Fe-Cr-Mo alloys may be described by an equation of the form:

$$\ln(CR) = -A \times (\text{Mo} + 0.5W) + B \quad (\text{Eq } 1)$$

where both A and B depend on the acid mixture.

It is possible that this behavior is determined by the relationship between the $(\text{Mo} + 0.5W)$ content and the exchange current density for the anodic dissolution and proton reduction reaction in the nonoxidizing acids. The decrease in anodic exchange current density by molybdenum results in an increase in the corrosion potential as a function of increasing molybdenum content. For the oxidizing acids, the effect of increasing chromium and molybdenum are both important, because the anodic curves are affected by two different but related mechanisms. The passive current density is reduced by increasing chromium and molybdenum, and the critical potential (the upper inflection point of the anodic curve) is increased by increasing chromium and molybdenum. The corrosion potential is determined by the intersection of the cathodic curve with the anodic curves. With

increasing chromium, the corrosion current density is reduced, because the passive current density is reduced. Assuming that the cathodic polarization is unaffected by chromium and molybdenum, the corrosion potential increases with an increase in chromium and molybdenum. The critical potential is also increased by molybdenum and chromium. The increase in critical potential by chromium and molybdenum would depend on factors such as temperature and concentrations of aggressive/inhibitive anionic species. Therefore, the effect of alloying elements in oxidizing solutions would be expected to be more complex.

The acid and acid-plus-salt mixtures can be classified into the following general categories, with an example of each:

- Nonoxidizing acid mixtures ($\text{H}_2\text{SO}_4 + \text{H}_3\text{PO}_4$)
- Nonoxidizing acids with halides ($\text{H}_2\text{SO}_4 + \text{HCl}$)
- Oxidizing acid mixtures without halides ($\text{H}_2\text{SO}_4 + \text{HNO}_3$)
- Oxidizing acid mixtures with halides ($\text{HNO}_3 + \text{HF}$)

Nonoxidizing solutions are commonly referred to as reducing solutions. However, the term *reducing acid* is not used here, because it implies that the acid reduces the metal, which is clearly not the case for metallic corrosion. In non-oxidizing acids, the main cathodic reaction is the reduction of proton, H^+ (or hydronium ion, H_3O^+ , for aqueous solutions), and the redox potential (open-circuit potential of a noncorroding electrode) generally follows the H^+/H_2 reduction equilibrium and kinetics. The presence of halides in these solutions generally does not lead to localized corrosion but can lead to high rates of active corrosion. While alloys that rely on passive film for corrosion resistance can perform adequately in nonoxidizing environments, the alloys that perform best in these environments also have low exchange current densities for anodic dissolution as well as cathodic reduction of hydrogen ions. In oxidizing acids or acid-salt mixtures, the cathodic reactions generate a redox potential higher than that of the proton reduction. In these environments, corrosion protection is afforded primarily by the passive film. The alloys that do not readily form a passive film (e.g., nickel-molybdenum and nickel-copper alloys) generally corrode at a high rate in oxidizing aqueous environments. The presence of halides can lead to localized corrosion of the passive alloys, depending on the alloy composition, the halides (Ref 3), and the other species in solution. In the absence of halides, the corrosion rates can be high if the redox potential is such that the transpassive regime is reached (e.g., chromic acid).

Nonoxidizing Mixtures

Reagent-Grade Phosphoric Acid Mixtures. The wet-process phosphoric acid is made

by reacting fluorapatite rock with sulfuric acid and then evaporating the dilute phosphoric acid in successive stages (Ref 4, 5). The resultant acid, usually referred to in P_2O_5 equivalents, is evaporated from 28% to as high as 54.9% P_2O_5 . The phosphoric acid contains varying concentrations of residual sulfuric acid, hydrofluoric acid, and fluosilicic acid. Chlorides, aluminum ions, ferrous/ferric ions, and other organic species also are present from the mineral and water used in the reactions (Ref 4–7). It is important to note that because of the presence of oxidizing impurities (especially Fe^{3+} and Al^{3+} ions) in the real-world wet-process acid, it can be an oxidizing acid. On the other hand, the presence of organic species can reduce the redox potential substantially. The corrosion performance of alloys in wet-process acid acquired from manufacturers is therefore highly variable but can be characterized as oxidizing (Ref 8).

Pyrolytic process (furnace-grade acid) is generally pure and nonoxidizing. The corrosion behavior of alloys in wet-process acids is described in the article “Corrosion by Phosphoric Acid” in this Volume. Several investigators (Ref 6, 7) have used reagent-grade phosphoric acid to understand the role of various residual impurities in phosphoric acid on corrosion. In these investigations, reagent-grade phosphoric acid was mixed with various concentrations of sulfuric, hydrofluoric, and fluosilicic acids. These mixtures are all nonoxidizing, as described in this section. Some claim that the synthetic acid mixtures adequately represent the commercial wet-process acid (Ref 5). These studies are typically based on a limited number of acids and alloys.

The effect of molybdenum in Ni-Fe-Cr-Mo alloys on the corrosion rate in reagent-grade mixtures of 75% H_3PO_4 (Fig. 1) is that:

- The corrosion rate decreases with an increase in molybdenum concentration, including alloys without any chromium, symptomatic of nonoxidizing environments.
- Addition of H_2SO_4 increases the corrosion rate slightly.
- Addition of hydrofluoric and fluosilicic acids significantly increases the corrosion rate.
- The effect of fluosilicic acid is much more significant than that of hydrofluoric acid (HF).

The last observation seems to be in apparent contradiction with the results (Ref 5) that indicated that HF is more aggressive than fluosilicic acid. Here, the effect of fluosilicic acid was measured in terms of the change in the passive potential range in a polarization curve. Such a change may not be directly correlated to corrosion rate.

Anodic polarization curves of type 317L stainless steel in reagent-grade phosphoric acid with additions of sulfate, chloride, and fluoride, among other cationic species, showed that chloride had a more pronounced effect than fluoride on the active region of the polarization curve, but fluoride had a more pronounced effect in the pseudo-passive region (Ref 7). The effect of a number of halides on the corrosion rate of 304 and 316 stainless steel in phosphoric acid is shown in Fig. 2. The rate for the molybdenum-containing 316 is lower than that for the non-molybdenum 304. Fluoride seems to have a much greater effect on corrosion than chloride. Bromide is considerably less aggressive than the

Fig. 1 Effect of molybdenum on corrosion rates in reagent-grade phosphoric acid mixtures at 149 °C (300 °F)

Fig. 2 Effect of F^- , Cl^- , and Br^- on corrosion rate of stainless steel in reagent-grade phosphoric acid at 80 °C (176 °F). (a) Type 304. (b) Type 316

other two halides. Such effects may be related to the stability of halide complexes in the acid.

The effect of alloying elements on corrosion can be fitted to a logarithmic relationship (Eq 1), where CR is corrosion rate in mils/yr, A is 0.15, B is 7 for the 75% H_3PO_4 + 3% H_2SO_4 + 0.1% H_2SiF_6 mixture, and B is 6.5 for the 75% H_3PO_4 + 5% H_2SO_4 + 1% HF mixture.

H_2SO_4 and HCl Mixtures. The effect of molybdenum plus tungsten on the corrosion rates of alloys in H_2SO_4 + HCl mixtures (Fig. 3) shows that increasing concentration of molybdenum results in a reduction in corrosion rate. For the chromium-containing alloys, which exhibit passive behavior, the effect of molybdenum may be attributed to its role in increasing the critical potential for localized corrosion for the chromium-containing alloys. For some chromium-containing alloys, only active behavior is seen in these acids. This is the case for type 316L stainless steel. The nickel-molybdenum alloys, such as alloy B-2, also do not exhibit significant passivity in these environments. In these cases, the beneficial effect of molybdenum may be attributed to a decrease in the exchange current density for anodic dissolution (Ref 9). It should be noted that even for the case of passive behavior and localized corrosion, the beneficial effect of molybdenum may be attributed to its effect on the active corrosion in the pit electrolyte (Ref 10). It should be cautioned that the use of alloy B-2 in these mixtures is predicated on the absence of oxidizing agents, such as dissolved iron. Based on the data (Fig. 3), the effect of alloying elements on the corrosion rate can be written in the form of Eq 1, where CR is corrosion rate in mils/yr, and A and B depend on the acid concentration. For 84% H_2SO_4 + 2.5% HCl mixture, A is 0.18 and B is 6.6.

The isocorrosion curves from data from two different sources for alloy G-30 are shown in Fig. 4. While the two sources tested at different temperatures and times, there is general agreement in the data trends. Certain regions of the data field are blocked because of lack of data for developing contours.

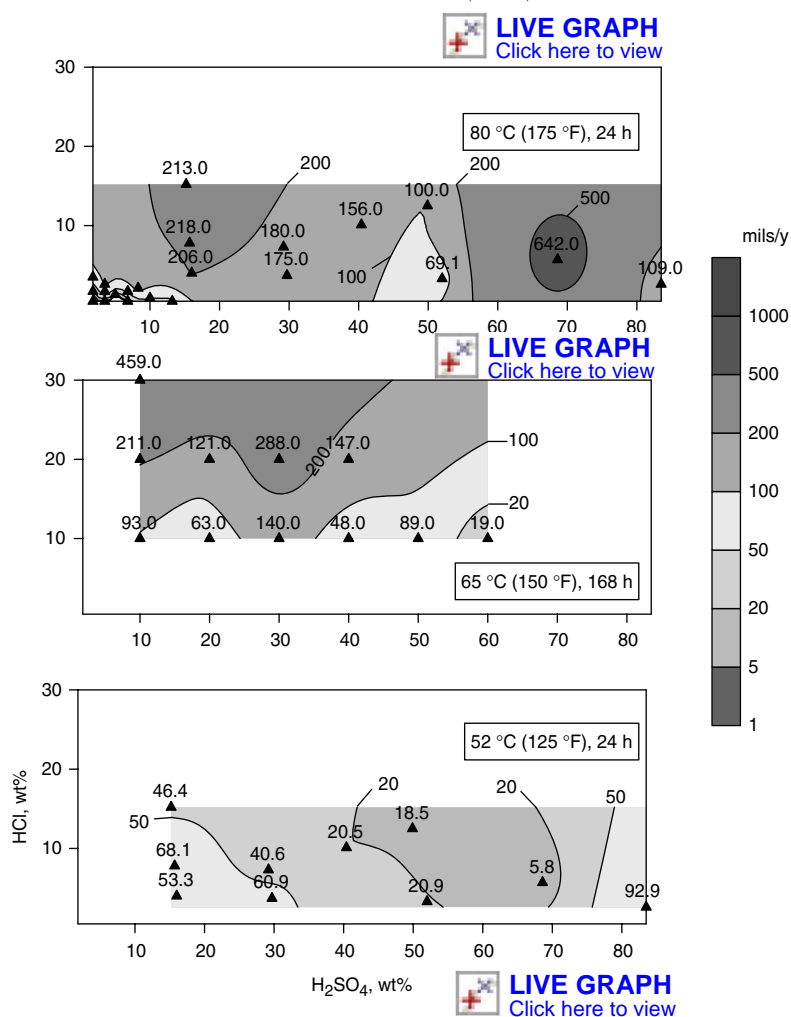

Fig. 4 Isocorrosion contours for alloy G-30 based on data from two sources. The temperatures are indicated within the figures. The numbers next to the symbols are test data. Contour values and test data are both mils/yr. Courtesy of Haynes International and Special Metals

One important aspect of corrosion behavior in mixed acids is the role of microstructural features of the alloy. This is especially true for duplex stainless steels. Generally, corrosion of duplex stainless steels in sulfuric acid occurs

preferentially in the austenite phase (Ref 11). However, when significant concentrations of chloride are present in sulfuric acid through the addition of HCl , corrosion occurs preferentially in the ferrite phase (Ref 11). If the ferrite phase is

continuous, high corrosion rates may be observed through grain dropping. An isocorrosion curve for a duplex stainless steel is given in Fig. 5.

H_2SO_4 and HF Mixtures. Unlike chloride ions, fluoride seldom promotes localized corrosion. Typically, increased active dissolution is observed in the presence of fluoride (Ref 12). The effect of fluoride ion on corrosion in a broad range of sulfuric acid concentrations was studied (Ref 2). Two examples of results for alloys 625 and G-30 are shown in Fig. 6. At concentrations below approximately 60 wt% H_2SO_4 , the addition of HF increases the corrosion rate of alloy G-30, whereas above 60 wt% H_2SO_4 , the addition of HF decreases the corrosion rate. Higher concentrations of HF lead to a greater decrease in corrosion rates. For the case of alloy 625, the change in the effect of HF occurs at a higher concentration of H_2SO_4 . It was found that in dilute sulfuric acid (10 wt%), the addition of HF resulted in complete depassivation and active corrosion. On the other hand, in 90 wt% sulfuric acid, the addition of HF resulted in a 3 order of magnitude decrease in current density and a broad passive region extending over 1 V. The increase in rotation speed of a rotating cylinder electrode served to increase passive potential range as well as decrease passive current density (Ref 2).

The effect of alloying elements Cr-Mo-W on corrosion rate in sulfuric acid with and without HF is seen in Fig. 7. In 20% sulfuric acid, the corrosion rate generally decreases with an increase in the level of chromium and molybdenum. It has also been shown previously that copper and nickel contents play a crucial role

Fig. 8 Effect of alloying elements on corrosion rates in acetic acid and NaCl mixtures. Boiling point of 100% acetic acid is 117.9 °C (244.2 °F). Boiling point of 100% acetic anhydride is 139.6 °C (283.3 °F).

Fig. 12 Effect of alloying element on corrosion rate in sulfuric and nitric acid mixtures

(Ref 13). Alloys containing nickel greater than approximately 34% perform significantly better than alloys with nickel less than this level. Within each of these two alloy classes, the corrosion rate seems to decrease with an increase in $Cr + Mo + 0.5W$. The correlation with just $(Mo + 0.5W)$ was poor for both acid concentration ranges. Copper has a smaller effect, and the effect reaches a plateau at approximately 1% Cu. As shown in Fig. 7, $Cr + Mo + 0.5W$ has a more significant effect on corrosion rates in dilute acid than in concentrated acid. The trend with alloying elements seems to be the same in $H_2SO_4 + HF$ mixtures, although HF increases the corrosion rates in dilute acids and decreases it in concentrated acids.

Acetic Acid Mixtures. In the absence of oxidizing salts, mixtures of acetic acid with

anhydride, NaCl, $FeCl_3$, $CuCl_2$, and $Fe_2(SO_4)_3$ exhibit the same relationship as other nonoxidizing acids. However, because of the low dielectric constant of the acid and the resultant low ion dissociation, the corrosion rates are lower than in comparable inorganic acids.

Figure 8 shows increasing molybdenum results in decreasing corrosion rates, symptomatic of nonoxidizing acids. The effect of alloying elements can be fit to a logarithmic relationship where CR is in mils/yr.

For the 88% acetic acid + Cl solutions, the effect of alloying elements is given by the following regression fit (coefficient of determination, $R^2 = 0.98$):

$$\ln(CR) = -0.26 \times (Mo + 0.5W) + 6.8 \quad (\text{Eq } 2)$$

For the 99% acetic acid + Cl, the effect of alloying elements may be given as (coefficient of

determination, $R^2 = 0.74$):

$$\ln(CR) = -0.24 \times (Mo + 0.5W) + 4.7 \quad (\text{Eq } 3)$$

As expected, for the acetic acid and anhydride mixture, the regression fit gives a similar slope as the more concentrated acetic acid (coefficient of determination, $R^2 = 0.72$):

$$\ln(CR) = -0.21 \times (Mo + 0.5W) + 4.5 \quad (\text{Eq } 4)$$

Formic Acid Mixtures. Formic acid can be regarded as a strong acid because of its relatively high dielectric constant. Therefore, the corrosion behavior of austenitic alloys in formic acid mixtures should resemble that in inorganic nonoxidizing acids. This is illustrated for two formic acid and NaCl mixtures in Fig. 9. For the 5% formic acid and 200 ppm Cl^- mixture, the corrosion rates are relatively low for most alloys, and there is significant scatter in the corrosion rates. However, for the 88 wt% acid, the corrosion rates decrease with $(Mo + 0.5W)$, similar to other nonoxidizing acids. The corrosion rate in this acid can be given by the

regression expression:

$$\ln(CR) = -0.23 \times (\text{Mo} + 0.5W) + 5.5 \quad (\text{Eq } 5)$$

Oxidizing Acid Mixtures

The effect of alloying elements in oxidizing acid mixtures is more complex than for non-oxidizing mixtures.

Wet-process phosphoric acid can range in its redox potential corrosivity, depending on the source of the rock. With a laboratory-simulated acid (50% P_2O_5 containing 4% SO_4^{2-} , 1% F^- , and 0.02% Cl^-), the addition of Fe^{3+} decreased the corrosion rate of type 317L stainless steel

dramatically, because the potential shifted from the active to the passive regime (Ref 7). On the other hand, if there is sufficient chloride present, then the presence of Fe^{3+} can increase corrosion rates. In wet-process phosphoric acid, this showed that the corrosion rates of stainless steels increased in the order 904L > 317L > 316L, indicating that both chromium and molybdenum played a role. A number of stainless steels in both plant wet-process acid and laboratory mixture simulating the plant acid were examined (Ref 6). The test results are plotted in terms of chromium and molybdenum contents of various alloys in Fig. 10.

Sulfuric Acid and Nitric Acid Mixtures. Small additions of nitric acid or nitrates can

decrease the corrosion rates of chromium-containing alloys in sulfuric acid (Fig. 11). The effect of nitrate generally depends on the chromium content of the alloy (Fig. 12). With the exception of the 26-Cr alloy, there is a decrease in corrosion rate with chromium content. The 26-Cr alloy is a duplex stainless steel with low nickel (5Ni), which may be the reason for the difference. Another possibility is the effect of microstructure in inducing interphase corrosion in the duplex stainless steel. No correlation with molybdenum or chromium and molybdenum contents was observed with these data.

The effects of temperature and acid mixture compositions on the corrosion rate of type 316L stainless steel are shown in isocorrosion diagrams (Fig. 13).

Nitric and Hydrofluoric Acid Mixtures.

These mixtures are commonly found in descaling baths and fluoropolymer processing. For the chromium-containing alloys, the corrosion rate appears to be a function of chromium, with molybdenum and tungsten playing a relatively minor role (Fig. 14). However, the nickel-molybdenum alloy (alloy B-2) was not as high as expected, although it is still such that its use is prohibited in this environment.

Nitric and Hydrochloric Acid Mixtures.

The effect of alloying elements on corrosion depends on the acid composition. This is illustrated in terms of isocorrosion diagrams as functions of chromium and molybdenum contents of the alloy (Fig. 15). Because some of the alloys have tungsten, the effect of tungsten is included in terms of its atomic concentration with respect to molybdenum. For the low nitric acid concentration solutions (<4% HNO_3), the corrosion rate decreases with an increase in molybdenum content. For the high nitric acid concentration, the corrosion rate increases with molybdenum concentration. Thus, high-molybdenum alloys may be detrimental in high nitric acid solutions containing chloride. Nitric acid additions to HCl cause two opposing effects that depend on the concentrations of both constituents as well as the alloy composition. Nitric acid (nitrate) helps in the repassivation of localized

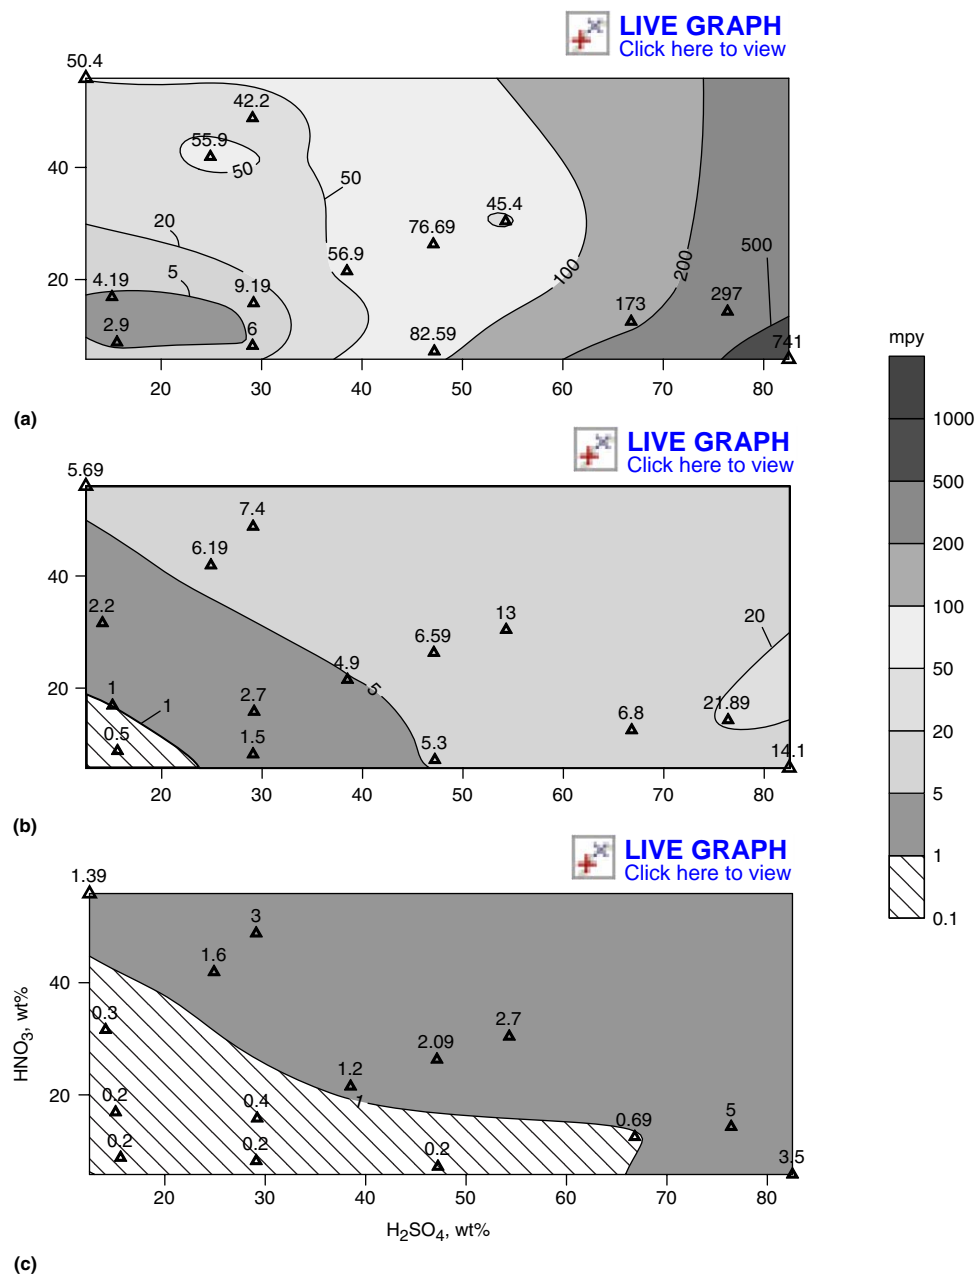

Fig. 13 Isocorrosion diagrams for type 316L in sulfuric acid and nitric acid mixtures. (a) Boiling. (b) 79 °C (175 °F). (c) 52 °C (125 °F)

corrosion and therefore inhibits corrosion. On the other hand, nitric acid also increases the redox potential of the solution and therefore increases the susceptibility to localized

corrosion. This results in a complex behavior of alloys in these mixtures.

Acetic Acid and Oxidizing Agents. Oxidizing agents containing chloride or other

halides have been known to exacerbate corrosion in acetic acid. The effect of FeCl_3 and CuCl_2 in glacial acetic acid on corrosion is shown as a function of $(\text{Mo} + 0.5\text{W})$ (Fig. 16). The corrosion rate in the same acetic acid in the presence of nonhalide ferric salt is quite low. Note that corrosion rate is not a good parameter for evaluating the behavior of chromium-molybdenum alloys because of localized corrosion. Nevertheless, because localized corrosion propagation was considerable, corrosion rate is used as a measure of relative susceptibility rather than actual penetration rate. In the 0.1% FeCl_3 -containing acid, all alloys exhibited significant corrosion. The B-2 nickel-molybdenum alloy shows uniform corrosion, because it does not form a passive film. In aqueous solutions with similar concentrations of Fe^{3+} , the corrosion rate of alloy B-2 would be significantly higher.

Although the redox potentials were not measured, it is likely that the redox potentials of the solutions with 0.03% FeCl_3 and 0.02% CuCl_2 were lower than the solution with 0.1% FeCl_3 . This may explain the lower corrosion rates of most alloys in the former mixtures. Also, alloy C-276 showed a significantly lower corrosion rate in the CuCl_2 solution, suggesting that the corrosion potential of this alloy in this solution was below the critical potential for localized corrosion. It can be seen (Fig. 17) that the effect of FeCl_3 on corrosion in acetic anhydride is less than in acetic acid but is nevertheless significant. Further characterization of the dissociation and redox kinetics is necessary in order to better interpret these results.

Corrosion by Organic Solvents

Hira S. Ahluwalia, Material Selection Resources Inc.
Ramgopal Thodla, General Electric Company

CORROSION is much less predictable in organic or mixed-solvent environments than in aqueous process environments. As a result, many chemical companies face greater uncertainty when selecting process equipment materials to manufacture chemical products using organic or mixed solvents than when the process environments are only aqueous. Chemical companies handle this uncertainty by overdesigning the equipment (wasting money and energy), rather than by accepting increased risks of corrosion failure (personnel hazards and environmental releases). Of particular interest to the chemical industry is the corrosion resistance of metals in organic solutions containing low concentrations of water and acid contamination. The corrosion of metals by organic solvents relevant to the chemical industry has received little systematic study; however, Ref 1 and 2 provide excellent information on this subject and are the basis for this article.

Classification of Organic Solvents

The structure and type of the organic functional group influences the reactivity of metals in organic solvents. The role of the organic solvent in many cases is to transport corrosive reactants and the corrosion precipitates formed during the corrosion process. The aggressiveness of the corrosive species is a function of the type of solvent used and their solvation properties. The various physical and chemical interaction forces acting during solvation can affect the corrosion behavior of various alloys in a given organic solvent or mixtures of solvents.

Aprotic and Protic Solvents. Organic solvents can be divided according to their properties and corrosivity into two general groups. These groups are referred to as aprotic and protic solvents. Aprotic solvents are water insoluble, whereas protic solvents are water soluble. The aprotic solvents can be further divided into two classes, nonpolar and dipolar. The nonpolar aprotic solvents include aromatic and aliphatic hydrocarbons and symmetrical halogenated hydrocarbons. Solvation in these systems occurs by relatively weak van der Waals-London forces.

The dipolar aprotic solvents include dimethyl formamide, propylene carbonate, acetonitrile, ketones, aldehydes, esters, and asymmetric halogenated hydrocarbons. The dipolar aprotic system displays electrostatic forces due to ion-dipole and dipole-dipole interactions. The protic solvents include organic acids, alcohols, amines, and amides. Solvation in protic solvents occurs through dipole-dipole interaction, ion-dipole interaction, and hydrogen bonding. The protic or aprotic character of the solvent is determined by the ability to provide protons. Protic media contain active hydrogen protons and have high conductivity and dielectric constants. The aprotic solvents do not contain active hydrogen protons and have very low dielectric constants and low conductivity. Table 1 shows examples of protic and aprotic systems with some of their characteristic physical properties (Ref 2).

One-Component and Multicomponent Systems. The classification of organic solvents into one-component and multicomponent systems provides a more phenomenological way of systematization (Ref 1). Pure organic solutions are considered one-component, whereas homogeneous mixtures with predominant organic components are considered as multicomponent. In one-component solvent systems, an oxidizing

group within the molecule structure is responsible for the corrosion process and the solvent and aggressive reagent are the same. Multicomponent systems generally contain the oxidizing species as solutes, and often the solvent and aggressive species are different. Tables 2 and 3 list examples of both classes. The corrosive species in one-component systems tends to consist of acidic hydrogen atoms of hydroxyl or carboxy groups as well as halogen atoms of halogenated hydrocarbons. These hydrocarbons have a strong affinity to electro-negative metals. In multicomponent systems, the corrosive species are similar to those in aqueous solutions and include oxygen, solvated protons, halogens, metal ions of higher valence, and other oxidizing compounds.

Corrosion in Aprotic (Water Insoluble) Solvent Systems

Aprotic solvents are essentially non-conductive and have very low solubility for water. The chlorinated solvent systems are of particular interest to the chemical industry

Table 1 Examples of aprotic and protic solvents and their physical properties

Solvent	Electrical conductivity, S/m	Solubility of water in solvent at 25 °C (75 °F), ppm	Dielectric constant	Boiling point	
				°C	°F
Aprotic solvents

Source: Ref 1

because hydrochloric acid (HCl) can be generated by thermal or hydrolytic degradation.

In dry aprotic solvent systems, even in the presence of acid constituents, corrosion

generally does not occur because the solutions are nonconductive and no electrochemical processes can take place. For example, bubbling up to 3 wt% HCl gas into dry trichloro-

ethylene does not corrode carbon steel or stainless steels in contrast to high corrosion rates that would be expected if the acid was in a water solution.

In the presence of low concentration of acids or water, corrosion in trichloroethylene becomes significant. If excess water beyond the solubility is present, two phases are formed resulting in the water phase becoming very corrosive because it extracts the acid from the solvent phase. If the water is dissolved, but less than 100 ppm in the presence of acid, little or no corrosion will be observed in the solution, condensing, or vapor zones. However, if the dissolved water is more than 200 ppm in the presence of acid, or if there is a small amount of phase water, minor corrosion would be expected in the solution, but severe corrosion may occur in the condensing zone. If the dissolved water exceeds about 600 ppm in the organic solutions, corrosion would be expected in the boiling solution and the condensing zone (Ref 2).

The corrosion resistance of several metallic materials of construction exposed to contaminated boiling trichloroethylene is tabulated in Table 4. The pH of the environment ranged from 0.5 to 2.5, and 200 to 600 ppm soluble water was present. The corrosion resistance of all the alloys tested was good when exposed to the liquid and vapor phase; however, significant corrosion was observed in the condensing zones. A nickel-molybdenum alloy (UNS N10001) and tantalum that normally have good corrosion resistance in hydrochloric solutions were the only alloys to show excellent performance in the condensing zone (Ref 2).

In aprotic solvent systems with chlorinated hydrocarbons, HCl, and H₂O as components, the degree of corrosion of unalloyed metals, stainless steels, and nickel-base alloys depends on the presence of critical concentrations of dissolved water and HCl of 200 and 40 ppm, respectively. The HCl and H₂O content should be kept below these critical values in order to avoid the two-phase state and maintain a low corrosion rate both in solution and in condensing areas. In the presence of water, the solvents trichloroethylene, 1,1,2-trichloroethane, and methylene chloride hydrolyze with a resulting buildup of acidity.

Table 2 Examples of one-component systems

Class of solvent	Example	Formula	Corrosive group

Corrosion in Protic (Water Soluble) Solvent Systems

Protic solvents have high dielectric constants and electrical conductivity and dissolve high levels of water. In contrast to aprotic systems, corrosion rate for many materials can be high in essentially water-free organic systems containing acids. The effect of water and acids has been studied in several protic organic solvents in several different metal systems (Ref 2). Table 5 shows the effect of water content on the corrosion of materials exposed to 0.5% wt HCl in dimethyl formamide (DMF). The data show that

a large reduction in corrosion rate occurs when the water content in HCl-acidified organic solvents exceeds 1 wt%. The amount of water required to inhibit corrosion depends on the alloy and on the level of acid present. The role of the water in these systems in forming and maintaining the passive film is thought to be important.

For example in case of tantalum, which is an extremely corrosion-resistant material, the presence of water in methanol solutions plays a strong role in corrosion resistance. The pitting and repassivation potential of tantalum are a strong function of water concentration as seen in Fig. 1. The pitting and repassivation potential increase sharply as the water concentration increases from 0.03 to 4 wt% (Ref 3).

Aeration and higher temperatures increase the corrosion rates in some cases even higher than in aqueous solutions containing the same level and type of acidity (Ref 4).

Importance of Conductivity

The difference in the corrosion characteristic of protic and aprotic solvents is not necessarily dependent on water content, but rather on the solution conductivity. Increasing the acidity or the soluble water content are merely ways to increase the solution conductivity. The corrosion data developed by Demo (Ref 2) correlating the corrosion rate with solution conductivities, acid content, and water content show quite clearly the importance of conductivity as the primary parameter determining the corrosivity of an organic solvent. Table 6 presents the relationship among solution conductivity, acidity, and corrosion rates of type 304 stainless steel in protic and aprotic solvents.

Based on the data in Table 6, corrosion will not occur in organic solvent solutions having a conductivity of less than about 10^{-5} S/m even with acid levels up to 1 to 3 wt%. If solution

conductivities are equal to or higher than 10^{-5} S/m, corrosion will be increasingly severe as the HCl content exceeds 40 ppm. For other acids the minimum acid content is higher. In low-conductivity solvent systems, the conductivity increases as the soluble water content increases. The conductivities approach 10^{-5} S/m when the water content is 200 ppm, thus leading to corrosion under appropriate acidic conditions.

Corrosion Testing

The basic types of corrosion processes are similar in both aqueous and organic liquid environments; however, special consideration must be given to the use of testing techniques to organic systems due to the complexity of the environment. The wide variety of organic liquids and mixtures increases the number of experimental variables that need to be considered and controlled. A review by Brossia et al. (Ref 5) discusses the important variables and parameters that require consideration when testing in organic systems.

Some of the important environmental variables that influence corrosion testing in organic liquids include:

- Metal, alloy, or nonmetallic material in contact with the organic solution
- Solution conductivity
- Solution acidity
- Water content of the solution
- Presence and stability of oxide or other preexisting films
- Type and concentration of surface contaminants or inclusions
- Functional group and concentration of organic solvent
- Solvent oxidation or reduction products
- Type and concentration of supporting electrolyte
- Applied potential
- Possible mechanistic paths for passivation
- Temperature

As in all corrosion testing, matching the test environment to the actual service environment is critical for obtaining useful information. In addition, by studying the effects of these variables on the corrosion processes, better insights into the controlling mechanisms, as well as the sensitivity of the corrosion processes to changes in the service environment, can be gained (Ref 5).

There are several aspects to conducting electrochemical tests in organic liquids that are often not encountered or important while testing in aqueous solutions. These include effects due to low solution conductivities, the importance of the water concentration in the solution, the existence of an extremely wide variety of liquid compositions, the complexity of products from electroactive organic liquids, and a lack of thermodynamic data (Ref 5).

Corrosion in High-Temperature Environments

George Y. Lai, Consultant

SOME MANUFACTURING PROCESSES require chemical reactions to proceed at high temperatures. High-temperature corrosion of the processing equipment by the processing stream can be a critical issue when making an alloy selection. High-temperature corrosion can result in a premature failure of the component. In some cases, contamination of the product by the corrosion products can also present a serious manufacturing problem. Thus, understanding the high-temperature corrosion behavior of alloys is an important step toward the selection of appropriate alloys for process equipment. Representative high-temperature equipment includes calciners, reactor vessels, pyrolysis furnace tubes, fired and process heater tubes, heat exchangers, waste heat boilers, and so on. Selection of a suitable alloy for the construction of the high-temperature equipment depends on a number of factors, such as mode of corrosion, type of equipment, operating temperatures, stresses, thermal cycling, materials properties, thermal stability of the alloy, corrosion allowable, and component design life and cost, among other factors. This article briefly describes the high-temperature corrosion modes that are frequently encountered in the chemical process industry. These corrosion modes include oxidation, carburization, metal dusting, nitridation, halogen corrosion, and sulfidation. More detailed treatments of these corrosion modes as well as other corrosion modes, such as ash/salt deposit corrosion, molten salt corrosion, and molten metal corrosion, can be found in Ref 1 and the articles "Molten Salt Corrosion," "Liquid Metal Corrosion," and "High-Temperature Gaseous Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Oxidation

The reactor (or calciner), where the chemical reaction is taking place in an oxidizing environment, can suffer oxidation attack in its internal diameter. Furthermore, the reactor (or calciner) is also subject to oxidation attack on the

outer diameter when heated from the outer diameter to allow the chemical process reaction to take place inside of the reactor (or calciner). Oxidation is also a critical issue in process heater or pyrolysis tubes, heat exchangers, piping, boilers, and numerous process equipment.

Carbon and chromium-molybdenum (Cr-Mo) steels are widely used for construction of high-temperature components, such as reactor vessels, calciners, heat exchangers, piping, boilers, and so on. Iron oxidizes to form magnetite (Fe_3O_4) and hematite or ferric oxide (Fe_2O_3) at temperatures up to 570°C (1060°F) and forms ferrous oxide (FeO), Fe_3O_4 , and Fe_2O_3 at temperatures above 570°C (1060°F). Carbon steels are generally not considered for applications above approximately 540°C (1000°F), due to decreased mechanical strength and increased scaling (accelerated oxidation). An early laboratory oxidation study (Ref 2) on carbon steel in air showed a wastage rate of approximately 0.3 mm/yr (12 mils/yr) at 595°C (1100°F),

as shown in Fig. 1. This was confirmed by a recent laboratory oxidation study in air (Ref 3) that showed the oxidation attack of 0.25 mm (10 mils) after one year at 595°C (1100°F).

Most oxidation data arise from laboratory testing that is commonly short term and isothermal. In actual plant services, components are subject to more complex service conditions, such as thermal cycling, overheating, heat fluxes, and the presence of various combustion species. Any of these conditions can accelerate oxidation rates. In addition, the high-temperature strength of the material decreases rapidly with increasing temperature. Furthermore, the alloy can undergo microstructural changes under long-term exposure to high temperatures. These microstructural changes can significantly degrade the material strength and properties. For example, carbon steel can suffer graphitization after exposure at 595°C (1100°F) in less than 1000 h (Ref 4). Chromium addition can improve the mechanical properties of steel and its resistance to

Fig. 1 Effect of chromium on the oxidation resistance of steels in air. Source: Ref 2

microstructural changes and oxidation attack (Fig. 1).

Stainless Steels. For components operating at higher temperatures, stainless steels that form a continuous chromium oxide scale (Cr_2O_3) offer good service. Because of their higher elevated-temperature strengths and their ease of fabrication and welding, austenitic stainless steels are much more widely used for the construction of high-temperature components than ferritic stainless steels. Chromium dictates oxidation resistance, with higher chromium content generally improving oxidation resistance for the alloy. The ASTM (ASME) specification range for chromium is 16 to 18% for type 316, 17 to 20% for type 321 and 347, 18 to 20% for type 304, 22 to 24% for type 309, and 24 to 26% for type 310. Type 310 is generally considered to be the best in the group, followed by type 309 and then those with lower chromium ranges. The benefit of chromium is dramatically illustrated in Fig. 2 (Ref 5). Testing was conducted at a very high temperature of 980 °C (1800 °F) in order to discriminate these stainless steels. The figure also shows that the stainless steels with lower chromium contents exhibited a shorter incubation time to breakaway oxidation than those with higher chromium contents. Breakaway oxidation occurs when the chromium oxide scale can no longer reform on the metal surface, thus causing the stainless steel to suffer rapid growth of iron oxides. As the chromium oxide scale grows with time, the chromium concentration in the matrix underneath the oxide scale decreases with increasing service time. The chromium concentration can be reduced to a level that is too low to maintain a protective chromium oxide scale. As a result, formation of nonprotective iron oxides and iron-chromium oxides is initiated, causing breakaway oxidation.

Fig. 2 Cyclic oxidation resistance of several stainless steels and nickel-base alloys in air at 980 °C (1800 °F). Source: Ref 5

Alloy producers tend to manufacture stainless steels to the bottom of the specification range for key alloying elements, such as chromium, to reduce materials cost in today's business climate. This is illustrated for type 304 (Ref 6):

	Cr, wt%	Ni, wt%
ASTM A 240, type 304	18.00–20.00	8.00–10.50
Pre-1965 heats	18.7	9.9
Current production	18.3	9.0

As a result, the chromium content can be insufficient to maintain a continuous chromium oxide scale during prolonged service or when subjected to thermal cycling or overheating conditions, thus promoting breakaway oxidation. These “lean” stainless steels can be further aggravated by the surface depletion of chromium resulting from the manufacturing process that may involve excessive pickling after black annealing (annealing in air or combustion atmosphere) during successive reductions in cold rolling in flat product manufacturing or pilgering in tubular manufacturing. In thin-gage sheet or tubular products, the reduced chromium concentration at the surface can be too low to form or maintain a continuous chromium oxide scale during service. As a result, iron oxides and isolated nonprotective iron-chromium oxide nodules develop on the metal surface, resulting in breakaway oxidation and unsatisfactory service.

Iron-Nickel-Chromium (Fe-Ni-Cr) and Nickel-Base Alloys. As the temperature increases to the temperature range where stainless steels can no longer meet both strength and oxidation requirements, it may be necessary to consider Fe-Ni-Cr and nickel-base alloys. Figure 2 shows significantly better cyclic oxidation resistance for nickel-base alloys in comparison with some stainless steels. Compositions of some of these alloys are tabulated in Table 1. In addition to increases in nickel and chromium, in some cases many alloys have used silicon or

aluminum along with rare earth elements, such as cerium, lanthanum, and yttrium, or the reactive element zirconium for improving the resistance to oxidation and other high-temperature corrosion attack. All the alloys listed in Table 1, except alloys 214 and MA 956, are chromia formers (alloys that form chromium oxide scales when heated to elevated temperatures). The small additions of these alloying elements enhance the protective nature of the chromium oxide scale. Addition of alloying elements, such as molybdenum and tungsten, increase elevated-temperature strength, which may be as important a design consideration as oxidation resistance as the service temperature increases.

At very high temperatures, 1100 °C (2010 °F) and higher, chromium oxide scales can suffer rapid growth, rendering them nonprotective. In addition, internal oxidation attack becomes severe at these temperatures. This is illustrated in Fig. 3 (Ref 7). The figure shows the oxidation morphology of alloy 601 after testing in air for 1056 h (44 days) at 850, 1000, 1100, and 1200 °C (1560, 1830, 2010, and 2190 °F). It is clear from the micrographs that the chromium oxide scales were no longer protective at 1100 and 1200 °C (2010 and 2190 °F). Alternate alloys for these applications will be alumina formers that form a protective aluminum oxide scale. Table 2 indicates oxidation data generated in air for 360 days at 1200 °C (2190 °F) in comparing an alumina former (alloy 214) with several chromia formers (Ref 8). Commercial alloys that are applicable at these temperatures are very limited. Wrought nickel alloy 214, when used at this temperature range, has adequate oxidation resistance; however, grain coarsening and lower creep-rupture strength can be significant issues. Oxide-dispersion-strengthened alloy MA 956, which is produced by a mechanical alloying powder process, exhibits adequate oxidation resistance and creep-rupture strengths. However, fabrication and joining of this alloy, as

well as cost, can be significant issues. Comparison oxidation data for some of the heat-resistant alloys are also available in technical publications (Ref 1, 3, 8) and alloy producers' technical data brochures (Ref 9–17).

In order to deal with the grain coarsening and relatively lower creep-rupture strengths that are associated with wrought alloy products at very high temperatures, engineers have the option of using castings. Because the manufacturing process does not involve forging and hot or cold rolling, casting alloys can be designed to contain large amounts of stable carbides and solid-solution-strengthening alloying elements for improving creep-rupture strengths. Furthermore, the cast product can be made with thicker walls to prolong service life. Many cast alloys contain large amounts of carbon along with tungsten, niobium, titanium, and rare earth elements. Cast alloys involving the addition of titanium and rare earth elements are commonly referred to as microalloyed products. Many reformers and pyrolysis furnace tubes are made of casting alloys. Table 3 lists some of the casting alloys.

Carburization

Metals and alloys are susceptible to carburization when exposed to environments containing methane (CH_4), carbon monoxide (CO), carbon dioxide (CO_2), hydrogen (H_2), or other hydrocarbon gases at elevated temperatures. Metals and alloys can also be carburized when in contact with graphite at elevated temperatures. An alloy is likely to be carburized when the carbon activity (a_c) of the environment is greater

than that of the alloy. Thermodynamic considerations for carburization are discussed in detail elsewhere (Ref 18, 19) and in the articles "Thermodynamics of Gaseous Corrosion" and "Kinetics of Gaseous Corrosion Processes" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. The carburization reaction generally follows the following steps (Ref 19):

1. Transport in the gas atmosphere by gas flow and diffusion in the boundary layer
2. Carbon transfer to the metal phase by phase-boundary reactions
3. Inward diffusion of carbon
4. Reaction of carbon with carbide-forming alloying elements in alloy interior

For step 2, addition of a small amount of sulfur to the process environment can significantly reduce the rate of carburization (Ref 19). For step 3, the composition of the alloy can be adjusted to decrease the diffusivity of carbon in the alloy interior, thus resulting in better resistance to carburization. Nickel reduces the diffusivity of carbon in Fe-Ni-Cr alloys (Ref 20). Accordingly, increasing nickel in Fe-Ni-Cr alloys improves the alloy carburization resistance, as shown in Fig. 4 (Ref 21).

Most high-temperature alloys form an adherent chromium oxide (Cr_2O_3) scale, which is considered to be an effective barrier against carbon ingress. Nevertheless, carburization has been encountered for chromia formers. Carbon permeation through the oxide scale occurs through pores and fissures in the oxide scale (Ref 22). Adding silicon to chromia formers can

significantly increase the alloy carburization resistance, as shown in Fig. 5 (Ref 23). Furthermore, aluminum oxide (Al_2O_3) scale is a significantly better barrier against carburization. This is illustrated in Fig. 6, which shows nickel-base alloy 214 (N07214) exhibiting essentially no evidence of carburization attack under the severe carburizing test condition (Ref 24). The figure also shows excellent carburization

resistance for alloy 602CA (N06025), which forms duplex $\text{Cr}_2\text{O}_3/\text{Al}_2\text{O}_3$ oxide scales.

Metal Dusting

Metal dusting typically occurs in carburizing environments containing primarily H_2 and CO . The corrosion attack is localized in the form of pitting. The dustlike corrosion products consist of carbon soot and powders of metals, oxides, and carbides. The temperature range for metal dusting attack is usually between 480 and 900 °C (900 and 1650 °F), with the maximum rate of attack occurring at 600 to 700 °C (1100 to 1300 °F), depending on the alloy and environment.

Significant advancement in understanding metal dusting behavior of alloys has been achieved in the past decade, with most of the contribution being made by Grabke and his co-workers (Ref 25–31). The thermodynamics and mechanisms of metal dusting were summarized

in his latest paper (Ref 31). Metal dusting can occur when the carbon activity (a_c) of the carburizing environment is greater than 1. The carbon transfer from the environment to the metal (iron and nickel and their alloys) results in oversaturation and disintegration into fine metal particles and graphite (Ref 31). The resistance to metal dusting attack of many high-temperature alloys has also been extensively investigated (Ref 25–37). Figure 7 shows an example of metal dusting attack for alloy 800 (Ref 32).

Researchers (Ref 32) reported metal dusting behavior of many commercial alloys, including Fe-Ni-Cr alloys and nickel-base alloys. The Fe-Ni-Cr alloys, such as 800H, HK40, and HP40, were found to suffer rapid metal dusting attack. Nickel-base alloys were found to be significantly better. Among nickel-base alloys, high-chromium alloys appeared to be much more resistant. Furthermore, aluminum addition to high-chromium nickel-base alloys appeared to be beneficial also. This is illustrated in Fig. 8 (Ref 32). Alloy 602CA (2.1% Al) was found to

be much more resistant to metal dusting than alloy 601, (1.4% Al), which, in turn, was much better than alloy 600 (0% Al). In this test, however, the 602CA test specimen was black annealed (pre-heat treated in air), while alloys 601 and 600 were in as-ground conditions. Pre-oxidation treatment of 602CA in air may have produced a duplex $\text{Cr}_2\text{O}_3/\text{Al}_2\text{O}_3$ oxide scale prior to the testing in the metal dusting environment. The effect of the surface condition of specimens on resistance to metal dusting has been investigated by several authors (Ref 27, 34). It has been found that the surface deformation due to grinding in the as-ground surface condition could significantly improve the resistance to metal dusting, because a better chromium oxide scale is formed. Figure 9 shows the metal dusting behavior of alloy 601 with various surface finishes, including a typical production product of the annealed and pickled condition (Ref 34). The specimen with as-ground surface finish exhibited the best resistance. The production sheet material with an annealed and pickled

condition was found to perform poorly. The process of black annealing and pickling could produce the surface condition with depleted chromium concentration at and near the surface. Equally unfavorable surface conditions were produced by black annealing, electrochemically polishing, or high-temperature solution annealing plus electrochemically polishing. A black-annealed surface for a chromia former, such as alloy 601, is not beneficial in developing favorable oxide scales to resist metal dusting. On the other hand, for an alumina former or an alloy containing both chromium and aluminum, a duplex $\text{Cr}_2\text{O}_3/\text{Al}_2\text{O}_3$ oxide scale may develop as a result of black annealing (preoxidation in air). Figure 10 summarizes the metal dusting test data up to 16,000 h of exposure for more than 30 commercial alloys (Ref 35). All the specimen surface conditions were in as-ground condition. The best alloy was found to be alloy 693, a newly developed nickel-base alloy containing 29% Cr and 3.1% Al with small amounts of niobium and zirconium.

It has been demonstrated that the as-ground surface provides additional improvement in resisting metal dusting attack. However, in terms of actual applications, it is unlikely that the tubing or the fabricated component is provided to the user for applications in the as-ground condition. However, one can take advantage of the favorable surface condition of the metal product if the general manufacturing processes are understood for different products in nickel-base alloys. For plate and some sheet products as well as some tubular products, the manufacturing process typically involves black annealing (i.e., annealing in air) and pickling. This type of surface finish is not desirable in terms of metal dusting resistance. Some sheet and tubular

products are cold rolled (cold pilgered for tubular products) and bright annealed (i.e., annealing in an inert environment, typically H_2 atmosphere). For chromia formers, the metal surface typically exhibits a shiny appearance with no preformed chromium oxide scale. Nevertheless, these products are expected to perform better than those processed by black annealing and pickling. For alumina formers as well as high-silicon alloys, however, the bright annealing tends to preform an aluminum-rich oxide scale or silicon-rich oxide scale for high-aluminum- and silicon-containing alloys, respectively. This is because the dewpoint for most of the bright annealing atmospheres is low enough to prevent the formation of Cr_2O_3 but high enough to form Al_2O_3 and SiO_2 . The bright-annealed surface condition for these two types of alloys can significantly improve the alloy resistance to metal dusting. This is illustrated in Fig. 11. HR-160 alloy (Ni-29Co-28Cr-2.75Si-0.5Ti) was shown to exhibit no metal dusting attack after testing for 10,000 h in H_2 -49%CO-2% H_2O at 650 °C (1200 °F). On the other hand, alloy 601 (Ni-23Cr-14Fe-1.4Al) was found to have suffered severe metal dusting attack. Test specimens of both alloys were obtained from bright-annealed sheet products. The bright-annealed sheet specimen of alloy 601 is believed to contain no preformed Cr_2O_3 oxide, while HR-160 bright-annealed sheet specimen most likely contained a preformed SiO_2 oxide film.

Nitridation

Metals and alloys are generally susceptible to nitridation when exposed to ammonia-bearing or nitrogen-base atmospheres at elevated tempera-

tures. Nitridation can cause the alloy to become embrittled. Many austenitic stainless steels have been used for processing equipment in ammonia-bearing environments. If the conditions are too hostile for stainless steels because of higher temperatures, higher ammonia concentration, or both, nickel-base alloys should be considered. Increasing nickel content in Fe-Ni-Cr alloys or Ni-Cr-Fe alloys increases the alloy nitridation resistance, as illustrated in Fig. 12 (Ref 1). High temperatures, 980 °C (1800 °F), for example, tend to result in the formation of internal nitrides, while low temperatures, 650 °C (1200 °F), for example,

Fig. 11 Optical micrographs showing the cross section of (a) alloy 601 and (b) alloy HR-160 specimens after laboratory testing at 650 °C (1200 °F) for 10,000 h in H_2 -49%CO-2% H_2O . cause nitride layer to form on the surface. Figure 13 shows a nitrided layer formed on the metal surface for type 304 stainless steel and alloy X (Ni-22Cr-9Mo-18.5Fe) when exposed to ammonia environment at 650 °C (1200 °F).

High-Temperature Corrosion by Halogen and Halides

Many metals and alloys are susceptible to severe corrosion attack when exposed to halogen gases at elevated temperatures. Halogen gases are very mobile species with high solubility and diffusivity that react readily with many metals and alloys to form metal halides, many of which exhibit high vapor pressures and/or low melting points. As a result, the metal-halogen reaction can proceed at a fairly rapid rate. Figure 14 provides a very general guideline for several alloys in dry chlorine environment (Ref 37). In chlorination reactions (i.e., the environment consisting of hydrogen chloride, HCl, with no oxygen present), nickel and nickel-base alloys, including molybdenum-containing nickel-base alloys, are much more resistant than iron-base alloys, as illustrated in Fig. 15 (Ref 38). For oxidizing environments containing Cl₂ (O₂-Cl₂

gas mixtures), molybdenum- (as well as tungsten-) containing nickel-base alloys were found to suffer higher corrosion attack, particularly at higher temperatures, as illustrated in Fig. 16 (Ref 39). When tested in Ar-20%O₂-2%Cl₂ at 900 °C (1650 °F), alloys 625 (9% Mo), X (9% Mo), 188 (14% W), C-276 (16% Mo, 4% W), and S (14.5% Mo) suffered higher corrosion rates than some simple Fe-Ni-Cr alloys, such as alloy 800H (which contains neither molybdenum nor tungsten). This was attributed (Ref 39) to the formation of oxychlorides of molybdenum and tungsten, which have very high vapor pressures. Also shown in Fig. 16, alumina-forming nickel-base alloys, such as alloy 214 (4.5% Al), performed very well in O₂-Cl₂ environments.

In F₂-containing environments without the presence of O₂, nickel is probably the best engineering material in resisting corrosion attack to fluorine gas corrosion, attributable to the formation of adherent nickel fluoride scale (Ref 40). Nickel is also the most resistant engineering material in hydrogen fluoride (HF) environments. Precious metals, such as gold and platinum, were found to be very resistant to high-temperature corrosion in HF environments (Ref 41). Nickel-molybdenum alloys, such as

alloy B-3, or Ni-Mo-Cr alloys containing low chromium, such as alloy 242, are much more resistant to high-temperature HF corrosion than nickel-chromium alloys, such as alloys 600, 617, and 602CA (Ref 41). Chromium in nickel-chromium alloys tends to cause internal attack by the formation of internal fluorides (Ref 42).

Sulfidation

Sulfidizing environments can best be categorized into three types: sulfur vapor and H₂-H₂S environments, oxidizing/sulfidizing environments, and SO₂-bearing environments. In sulfur vapor and H₂-H₂S environments, the oxygen potentials (P_{O₂}) are so low that iron and chromium oxides are not thermodynamically stable. Under these conditions, alloys form sulfide scales, and the alloys that form chromium sulfide scales are more resistant than those forming iron sulfide scales. Thus, increasing chromium generally improves the alloy sulfidation resistance. Some of the sulfidation data generated from these environments are available elsewhere (Ref 43–45).

In oxidizing/sulfidizing environments (also referred to as reducing, mixed-gas environments), which typically consist of H₂, CO, CO₂, H₂O, H₂S, and so on, there are generally sufficient oxygen and sulfur potentials (P_{O₂}, P_{S₂}) to form oxides and sulfides for most high-temperature alloys, particularly chromia formers. The corrosion reaction in these environments generally involves oxidation and sulfidation. In most cases, the alloy remains protected during the initial oxidation period until breakaway corrosion is initiated, which is then followed by rapid sulfidation attack.

Higher-nickel-content alloys are most susceptible to sulfidation attack. Decreasing nickel content in nickel-base alloys generally reduces

Fig. 17 Sulfidation behavior of type 347 stainless steel, alloy 800H, alloy HR-120, alloy 556, and alloy HR-160 in H₂-7%CO-1.5%H₂O-0.6%H₂S (oxygen potential, P_{O₂} = 10⁻²³ atm; sulfur potential, P_{S₂} = 10⁻⁹ atm; carbon activity, a_c = 0.3-0.4). Source: Ref 45

susceptibility to sulfidation attack. Chromium oxide scale is generally protective against sulfidation. Increasing chromium content in iron-, nickel-, and cobalt-base alloys improves sulfidation resistance. For severe sulfidizing environments (i.e., high temperatures, high P_{S₂}, low P_{O₂}), chromium content should preferably be higher than 25%. Other beneficial alloying elements include cobalt, silicon, aluminum, and titanium. Formation of a duplex Cr₂O₃/SiO₂ oxide scale offers a very effective barrier to sulfidation attack in nickel-base alloy HR-160, as illustrated in Fig. 17 (Ref 45). Another commercial nickel-base alloy containing high chromium and silicon is 45TM, which is also reported to provide excellent sulfidation resistance (Ref 46).

Environments containing SO₂ are generally highly oxidizing. However, sulfides tend to form internally underneath the chromium oxide scales. A test was performed (Ref 47) to examine the corrosion behavior of cobalt-bearing alloy 556 and type 304 stainless steel in Ar-5%O₂-5%CO₂ and Ar-5%O₂-5%CO₂-10%SO₂ environments at 980 °C (1800 °F) for 550 h. Test results suggested that an alloy that formed a protective oxide scale in a purely oxidizing environment would form a similarly protective oxide scale in SO₂-O₂ environments. Chromium, again, is a very effective alloying element in improving the alloy sulfidation resistance.

Corrosion in the Pulp and Paper Industry

Harry Dykstra, Acuren*

THE \$165 BILLION Pulp, paper and allied products industry supplies the United States with approximately 300 kg (660 lb) of paper per person every year. More than 300 pulp mills and 550 paper mills support its production. The total direct annual cost of corrosion is estimated at U.S. \$6 billion and these costs will likely increase. The infrastructure of North American producers has not been replaced because most new production has been located to South America and South East Asia. The North American mills face tough competition from lower cost areas of the world with the result that extending the life of existing mill equipment has offset funding for capital projects. Increased efficiencies are often realized through process changes that require modification of existing equipment to function under environments that it was not specifically designed for. An understanding of the corrosion mechanisms active in the pulp and paper industry is essential for successful maintenance and operation of these plants as the operating conditions evolve and the infrastructure continues to age.

The pulp and paper processes require a myriad of materials and fabrication methods to provide service in a mixture of organic and inorganic environments that range from atmospheric to boilers producing molten smelt under controlled reducing conditions. The pH ranges from near 1 in acidic, oxidizing bleach environments to 14 in hot digester liquors. Often, mills using the same process can have completely different corrosion issues due to site-specific conditions that develop based on the type of wood being processed, on the chemicals used in different parts of the process, corrosion control measures that have been introduced and the age of the equipment. The operating conditions at one location can be altered due to process modifications that are made at other locations in the mill. As a result, unlike many other chemical industries, historical data of process equipment in the pulp and paper industry is no predictor of future materials performance.

Areas of Major Corrosion Impact

Corrosive environments are found in a number

of process stages in the pulp and paper industry including:

- Pulp production
- Pulp processing and chemical recovery
- Pulp bleaching
- Paper manufacturing

Each manufacturing step has its own corrosion problems related to the size and quality of the wood fibers, the amount of and temperature of the process water, the concentration of the treatment chemicals, and the materials used for machinery construction.

Pulp Production

There are several different methods of pulp production to make different strengths and grades of paper. The most common classifications are chemical, mechanical, and semi-chemical pulping techniques.

Chemical pulping uses various chemicals to produce long, strong, and stable fibers and to remove the lignin that bonds the fibers together. The chemicals used will vary depending on the type of chemical pulping used. In North America, there are two main types of chemical pulping performed: kraft pulping, which is also referred to as sulfate pulping, and sulfite pulping.

The kraft process starts with feeding wood chips into large pressure vessels called digesters (see the section "Corrosion of Digesters" for details). Chips are cooked under pressure in a steam heated aqueous solution of sodium hydroxide (NaOH) and sodium sulfide (Na₂S), also known as white liquor. The spent pulping liquor, called black liquor, is concentrated by evaporation and burned to generate high-pressure steam for the mill processes. The inorganic portion of the black liquor is then used to regenerate the NaOH and Na₂S needed for pulping.

The kraft process is the predominant pulping process used in North America to extract fibers from wood for use in the manufacture of paper, tissue, and paperboard (approx-

mately 80% of pulp is produced by the kraft process). The term "kraft" is derived from the German word for strong, which reflects the high strength of paper products derived from kraft pulp. The high strength, together with effective methods of recovering pulping chemicals, explains the popularity of kraft pulping. Emphasis in this article has been placed on the corrosion problems associated with the kraft process.

The sulfite pulping process uses cooking liquors of sodium bisulfite or magnesium bisulfite in a pulp digester with a pH of 3. It is generally considered more corrosive than the kraft process environment. See the section "Corrosion in the Sulfite Process" for details.

Mechanical Pulping. In mechanical pulping, wood fibers are separated from each other by rolling, rubbing, or teasing, either against themselves, or against a harder, specially designed surface. Chemical additions or the application of heat and pressure can be used to increase the efficiency of the process, but the predominant pulping forces are mechanical. See the section "Corrosion Control in High-Yield Mechanical Pulping" for details.

Semichemical pulping techniques use weak chemical solutions of sodium sulfite (Na₂SO₃) and sodium carbonate (Na₂CO₃) to help digest the lignin in the pulp. See the section "Corrosion Control in Neutral Sulfite Semichemical Pulping" for details.

Pulp Processing and Chemical Recovery

To recover chemicals from the black liquor, the slurry goes through a chemical recovery process. The liquor passes through evaporators, recovery boilers, and causticizers to eventually produce white liquor that is recycled back to the digester. See the sections "Corrosion Control in Chemical Recovery" and "Corrosion in Recovery Boilers" for details. A by-product of the kraft black liquor process is tall oil, which is refined and used in paint varnish, linoleum, drying oils, emulsions, lubricants, and soaps.

Tuthill, Tuthill Associates; Douglas Singbeil, Paprican; Randy Nixon, Corrosion Probe, Inc.

See the section "Corrosion Control in Tall Oil Plants" for details.

Pulp Bleaching

Pulp bleaching is performed on the pulp in order to increase its brightness. Bleaching is an extremely corrosive process that is carried out under acidic conditions with strong oxidants such as elemental chlorine (Cl_2), chlorine dioxide (ClO_2), ozone (O_3), sodium hypochlorite (NaClO), oxygen (O_2), and hydrogen peroxide (H_2O_2). In recent years, chlorine-free bleaching operations have been developed. This has resulted in major changes in materials selection for bleach plants. See the section "Corrosion Control in Bleach Plants" for details.

Paper Manufacturing

Using a paper production machine, the processed pulp is converted into a paper product. At the beginning of this stage, the water content of the paper is greater than 99%. In the wet-end operation, the slurry of pulp is deposited onto a continuously moving belt that suctions the water from the slurry using gravity, vacuum chambers, and vacuum rolls. The continuous sheet then moves through additional rollers that compress the fibers and remove the residual water. See the sections "Paper Machine Corrosion" and "Suction Roll Corrosion" for details of the corrosion problems encountered in the wet end of a paper machine.

Following the pressing of the wet-end operations, the continuous sheet is compressed by steam-heated rollers to allow the fibers to begin bonding together. Coatings are then applied to enhance the surface appearance before the sheet is spooled for storage. Because corrosion is not a serious concern with these dry-end operations, this subject is not addressed further in this article.

Environmental Issues

Environmental issues involving the pulp and paper industry require that water usage by pulp and paper mills be reduced because they are among the largest industrial process water users in North America. Today, the pulp and paper industry uses a lower volume of process water, recycles and reuses more water, and cleans water before releasing it, all in an effort to reduce costs as well as responding to increasingly strict environmental regulations. Such efforts, unfortunately, can sometimes create additional corrosion-related problem. See, for example, the section "Wastewater Treatment Corrosion in Pulp and Paper Mills."

Similarly, air quality emission standards have been made more strict and pulp mills are now required to reduce the amount of sulfur compounds released to the atmosphere. This has also led to corrosion problems as discussed in

the section "Corrosion Control in Air Quality Control."

Corrosion of Digesters

Angela Wensley,
Angela Wensley Engineering

In the kraft process, hot alkaline (sodium sulfide and sodium hydroxide) liquid is used to dissolve the lignin from wood chips and to separate individual wood fibers for use in paper-making. Wood chips are exposed to cooking liquors for several hours at elevated temperature and pressure in a process called digestion. Digestion may occur by repetitive batch processes in batch digesters, or the process may occur continuously in continuous digesters. This section describes both types of digesters, their materials of construction, corrosion problems encountered, and methods to protect digesters from corrosion. Ancillary equipment to digesters is also discussed.

Batch Digesters

A typical batch digester consists of a vertical cylindrical vessel with a hemispherical or ellipsoidal top head and a conical bottom, as shown in cross-sectional view in Fig. 1. Batch digesters are typically 2.4 to 4.0 m (8 to 13 ft) in diameter and up to 18.3 m (60 ft) high. Soft or hard wood chips are fed into the top of the vessel, along with hot cooking liquor, which helps pack the chips in the vessel. The liquor consists of a mixture of white and black liquors in various volume ratios depending on the pulp product being manufactured.

After filling with wood chips and liquor, the vessel is closed and cooking begins, with heat supplied by direct injection of steam (Fig. 1a) or by indirect steam heating (Fig. 1b) in an external heat exchanger. A typical batch cook lasts about 2 h. The cooking temperature of approximately 170°C (338°F) is reached after about 1 h. At this time, direct steaming is usually stopped. Some facilities remove the liquors and pulp by displacement instead of blowing, but this is not a common practice.

At the end of the cook, the pulp is blown from the bottom of the vessel into a blow tank. From there the pulp goes to brown stock washers where the spent cooking liquor is separated from the pulp. Steam from the blow tank is removed for heat recovery and condensed in brown stock wash water.

Over the years there has been a trend to increase production by decreasing batch cook times. This requires the use of higher ratios of white-to-black liquor and higher temperatures. Both these practices cause increased corrosion

rates in both carbon steel and stainless steel digesters.

Materials of Construction

Although there is a trend to construct batch digesters from solid duplex stainless steels, most batch digesters have been constructed from carbon steel with generous corrosion allowances (≥ 19 mm, or 0.75 in.), such that they can remain in service for perhaps 10 years before some means of protection must be used. In the 1950s and 1960s, digesters in North America were constructed using a modified low-silicon (0.02% Si max) grade of ASTM A 285 carbon steel, with low-silicon welds on the process side. Today (2006) most new carbon steel batch digesters are made from ASTM A 516 grade 70, a higher-strength, pressure vessel steel in which the silicon content is controlled in the range 0.15 to 0.30% Si, and without low-silicon weld caps. Higher-silicon steels corrode more rapidly in alkaline pulping liquors.

Numerous batch digesters have been constructed from clad plate (either roll- or explosion-bonded) with stainless steel on the inside and carbon steel on the outside. Types 304L (S30403) and 316L (S31603) stainless steels have been most commonly selected for clad plate (although these experience corrosion). Some batch digesters have been constructed with a stainless steel weld overlay lining, although this practice is not common. Stainless steel weld overlays are discussed in some depth in this section under "Protection of Batch Digesters." Some have been constructed of cold stretched type 304 (S30400) stainless steel in accordance with the Swedish cold stretching code.

Duplex stainless steels in either solid or clad form have been used for several years for construction of new batch digesters worldwide.

Fig. 1 Two types of batch digesters. (a) Direct-heating digester. (b) Indirect-heating digester

North America has been slow to adopt these materials, but the number of new duplex stainless steel batch digesters is expected to increase. The most common duplex alloy used for duplex digester construction is S32205 (formerly known as S31803 and commonly known as "alloy 2205"). Due to their higher strength, duplex stainless steel digesters may be significantly thinner than carbon steel digesters designed to hold the same pressure.

Corrosion

Corrosion of carbon steel kraft batch digesters has been a known problem for more than 50 years. Pioneering work (Ref 1–6) revealed that the silicon content of the steel controlled the corrosion rate of digester steels, with higher contents being increasingly susceptible. Carbon steel batch digesters do not corrode uniformly and often experience the most corrosion in an inverted horseshoe-shaped pattern where the liquor contacts the wall during filling (Ref 7). The zone of most severe corrosion varies from mill to mill, and perhaps from digester to digester. In most digesters the corrosion is most pronounced in the cylindrical section. In other digesters it is worse in the bottom cone; in yet others, in the top dome.

Corrosion of stainless steels (both in wrought form and weld overlays) is primarily a function of the chromium content of the overlay. Austenitic stainless steel grades such as type 316L (16 to 18% Cr) and type 304L (18 to 20% Cr) can experience rapid corrosion, up to 1 mm/yr (40 mils/yr). With its higher chromium content, type 304L performs better in digesters than type 316L. Work by Audouard to investigate corrosion during "hot plate boiling" has revealed that duplex stainless steel with even higher chromium content (22 to 27% Cr) resists corrosion better than conventional austenitic grades (Ref 8–12). Corrosion testing has also shown that molybdenum is not a beneficial alloying addition for corrosion resistance of stainless steels in digester liquors.

Stainless steel weld overlays with low chromium content can also experience rapid corrosion. Conventional type 309L (S30980) stainless steel weld overlays may have an as-deposited chromium content of 20%, which is higher than for type 304L but is still insufficient for corrosion resistance in aggressive batch digester environments. Corrosion testing in several batch digester liquors has revealed that at least 25% Cr is required for stainless steel weld overlays to have best corrosion resistance in aggressive digester environments (Ref 13). Duplex stainless steel weld overlays such as type 312 (S31200) can give 22% to 28% Cr when applied over a carbon steel substrate, depending on the welding process and mode employed.

Early work (Ref 14) suggested that lower-than-intended chromium content resulted in poor weld microstructures, which in turn corroded (Fig. 2). More recent work has focused on the

role of chromium content on overlay corrosion. Technical Association of the Pulp and Paper Industry (TAPPI) guidelines give minimum as-deposited chemistry requirements for austenitic stainless steel weld overlays, along with criteria for soundness and structural uniformity. However, even weld overlays that meet the minimum of 18% Cr in the TAPPI guideline can experience rapid corrosion in many batch digesters (Ref 15). Another problem with stainless steel weld overlays is that once the overlay is penetrated (e.g., at a pinhole), the underlying carbon steel can corrode at a great rate, producing a large cavity that can grow completely through the digester wall.

Although duplex stainless steels resist corrosion in digesters better than conventional austenitic stainless steels (Ref 8–13), duplex stainless steels can experience selective corrosion of the austenite phase in the microstructure because this phase is lower in chromium content than the ferrite phase (Ref 16). Olsson reports very low corrosion rate—approximately 0.1 mm (5 mils) after 3 years in service—where selective phase corrosion has occurred (Ref 17). For particularly aggressive batch digester environments, superduplex stainless steels (such as S32750) have superior corrosion resistance because the ferrite phase has a higher chromium content than that in conventional grades (such as S32205). The modern trend is to construct new batch digesters from duplex stainless steels (Ref 18, 19). The higher strength and low corrosion allowance for duplex materials allow thinner walls to offset much of the higher cost compared to carbon steel.

Protection of Batch Digesters

Thinned carbon steel digesters are most commonly protected by application of a layer of stainless steel weld overlay (Ref 14, 20–24). Weld overlay has also been applied to extend the service life of digesters with corroded stainless steel cladding or with corroded overlay. Other protective measures include application of thermal spray coatings (Ref 16) and anodic protection (Ref 25–27). Buildup with carbon steel weld metal is not considered to be a protective option, as such buildup (e.g., E7018) characteristically has high silicon content and typically corrodes much faster than the original digester wall. However, buildup of very thin sections with carbon steel before applying stainless steel overlay or thermal spray coating is good practice and normally done.

Stainless steel weld overlays are best applied before the corrosion allowance has been completely consumed. TAPPI TIP 0402-03 "Guidelines for Corrosion Resistant Weld Overlays in Sulphate and Soda Digester Vessels" provides much useful information (Ref 28). These overlays are applied automatically using either the submerged arc welding (SAW) process or the gas metal arc welding (GMAW) process. Other welding processes may be used for pickup repairs or for smaller areas of overlay, such as

around projecting nozzles where automatic equipment does not work.

A SAW overlay is typically applied horizontally, with twin electrodes traveling around the circumference of the digester; the second electrode follows behind the first, completely remelting the deposit. A GMAW overlay can be applied either horizontally ("conventional" overlay with a single electrode) or vertically over lengths up to 4 m (13 ft), with single or dual torches.

Horizontal weld overlay has been the "conventional" overlay mode for more than 40 years and typically gives an overlay thickness of 6 mm (0.25 in.), for either the SAW or GMAW processes, with a minimum of 4.8 mm (0.188 in.) overlay thickness. The vertical down mode typically gives an overlay with a nominal thickness of 4.8 mm (0.188 in.) and a minimum thickness of 2.5 mm (0.100 in.). Vertical overlay may be suitable in certain batch digesters if it can be established (either by corrosion testing or by service experience) that the overlay alloy does not corrode rapidly in the particular liquor environment.

The as-deposited composition of a weld overlay is a result of the dilution of the filler metal with the substrate. For overlay on carbon steel, dilution with the carbon steel results in a lower alloy content than that of the wire or electrode. For overlay on stainless steel (or for two-layer overlay), the as-deposited composition may be close to that of the wire or electrode.

In the past, most stainless steel weld overlays in digesters were type 309 with 20 to 23% Cr and 10 to 12% Ni in the weld deposit. For SAW overlay, the wire and flux are specially manufactured to provide the desired as-deposited chemistry. For GMAW overlay, type ER309LSi (S30988) wire has been widely used.

In recent years there has been an increasing interest in application of type 312 duplex stainless steel weld overlays. The SAW wire and flux chemistries that give as-deposited compositions resembling type 312 stainless steel are available.

Fig. 2 Typical problems with digester weld overlays. Accelerated corrosive attack on a stainless steel weld overlay lining in a kraft pulp digester vessel after 18 months of service. Localized furrow attack occurs between weld beads displaying rapid-etching (lean alloy) structure. Deposited by submerged arc process (E-310 electrode).

A GMAW overlay can be done with ER312 wire. Internal microcracking has occurred in some type 312 overlays. Provided the internal microcracks are not exposed to the surface, there is little driving force for their growth and no way for them to act as paths for liquor to gain access to the carbon steel substrate.

Overlays made with either type 309 or 312 stainless steels have microstructures consisting of a mixture of austenite and ferrite. Conventionally, however, the type 309 overlays have been called "austenitic" because they have lower ferrite than their type 312 counterparts, which are termed "duplex." The SAW overlays tend to have higher ferrite contents than their GMAW counterparts. The presence of ferrite in the microstructure of stainless steel weld overlays is highly desirable. Stainless steel overlays with less than 3% ferrite are prone to hot cracking, particularly if sulfur is present as a contaminant.

Thermal Spray Coatings. Many batch digesters have been protected from corrosion by the application of thermal spray coatings. Most coating alloys are either alloy 625 (N06625) or similar alloy, but with somewhat lower molybdenum content. The predominant process for applying these coatings has been twin-wire arc spray (TWAS). In recent years, coatings have also been applied by the high-velocity oxygen fuel (HVOF) process.

Twin-wire arc spray coatings are typically applied 2 mm (80 mils) thick to overcome the porosity inherent in that process and to prevent liquor access to the carbon steel substrate. High-velocity oxyfuel coatings are characteristically much less porous and are applied thinner (e.g., 0.6 mm, or 25 mils).

Thermal spray coatings are maintenance coatings inasmuch as they typically have a service life of up to 8 years before recoating is required. The main advantage of thermal spray coatings is that they introduce no significant heating, and thus there are no heat-affected zones (HAZs) as with welds and no distortion or delamination of the vessel (as sometimes happens with weld overlays).

In-service problems with thermal spray coatings include disbonding and blistering. The bond to the carbon steel substrate is mechanical, and poor surface preparation can lead to poor bonding. The blistering is believed to be caused by osmotic pressure buildup when liquor permeates the coating.

Anodic Protection. Monitoring corrosion potential in carbon steel batch digesters has revealed that the potential cycles change from active to passive over the course of a cook (Ref 29). With anodic protection, an external rectifier and internal cathodes are used to supply current to the digester wall, thus raising the corrosion potential more rapidly to the passive zone. Although the concept of anodic protection of batch digesters has been understood for many years, there are as yet no anodically protected batch digesters in North America. However, there are numerous anodically protected continuous digesters in Finland.

Anodic protection is only able to protect the digester wall below the liquor level. For those digesters where corrosion of the top dome is the problem, anodic protection would be of no benefit.

Continuous Digesters

Continuous digesters first appeared commercially in the late 1950s. Figure 3 shows a schematic flow diagram for a typical continuous digester, the majority of which are of a "Kamyr" design. A prominent feature of most Kamyr systems is a cylindrical digester shell, having a vertical axis and a length-to-diameter ratio ranging from about 5-to-1 to 15-to-1. The shell diameter typically decreases from bottom to top with a series of conical transitions. The top and bottom heads are ellipsoidal.

As the chips descend through the digester, they are impregnated with liquor, cooked, washed, and discharged into a blow tank. The spent liquor is extracted through extraction screens. Heat is supplied by indirect heating of the cooking liquor in external heat exchangers. Continuous digesters can be either of "hydraulic" (filled to the top with cooking liquor) or "vapor phase" (with steam injection in the top) design. The hydraulic digester is by far the predominant type.

Digesters can also be single-vessel or two-vessel systems. In two-vessel systems, there is a separate impregnation vessel, with cooking, extraction, and washing done in the digester. For this section, the term "digester vessel" refers to

either the single-vessel or two-vessel systems, including the impregnation vessel.

In conventional operation the cooking liquor (a mixture of white and black liquors) is added in the top of either the digester (for single-vessel systems) or impregnation vessel (for two-vessel systems). In extended delignification processes such as modified continuous cooking (MCC), extended modified continuous cooking (EMCC), isothermal cooking (ITC), or low-solids cooking, white liquor is added lower in the digester. The extended delignification processes are also characterized by higher temperatures in the bottom of the digester (e.g., below the extraction screens).

Materials of Construction

The pressure shell of the earliest continuous digesters were built of low-silicon ASTM A 285 grade C carbon steel "modified for digester service," together with low-silicon caps for the process-side welds. In the late 1960s, medium-silicon steels such as A 516 grade 70 became the predominant material of construction for continuous digesters, and the use of low-silicon weld metal was discontinued.

Some of the nonpressurized internal equipment in continuous digesters have traditionally been constructed from type 304L stainless steel. This includes the central pipes, screens, and internal cone. Many of the nozzles in carbon steel digesters are also type 304L stainless steel. There is a recent trend to replace corroded carbon steel blank plates with type 304L stainless steel blank plates and type 304L standoff rods on the back.

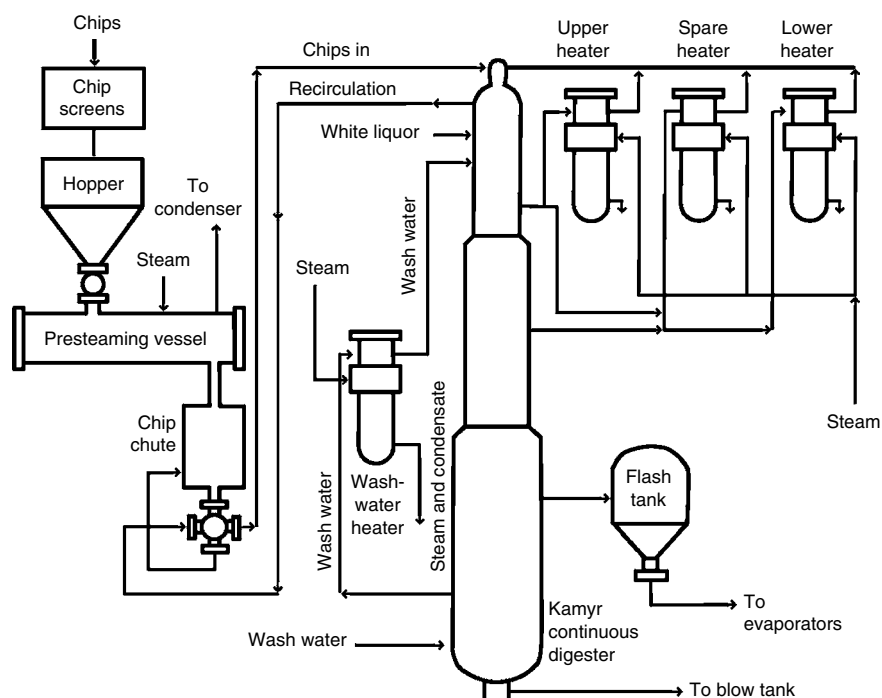

Fig. 3 Kamyr continuous digester

Several continuous digesters have been constructed from roll-clad plate with type 304L stainless steel on the process side and A 516 grade 70 carbon steel on the outside. Indeed, most digesters have also been constructed with type 304L stainless-clad top and bottom heads, either as a loose liner or with roll-clad plate.

Some new continuous digesters have been built from duplex stainless steel (S31803). This alloy is quite resistant to corrosion in continuous digester environments (Ref 13, 16). Duplex stainless steel has also been used for the replacement of one digester top.

Corrosion

The most serious corrosion problem with carbon steel continuous digesters has been caustic stress-corrosion cracking (SCC) of un-stress-relieved seam welds in the impregnation zone or in the impregnation vessel for two-vessel systems (Ref 30–40). The ASME Boiler and Pressure Vessel Code (Ref 41) does not require postweld stress relief treatment for wall thicknesses less than 32 mm (1.25 in.), which often is the case at the top of continuous digesters. In 1980 there was catastrophic caustic SCC failure of an un-stress-relieved top section of a continuous digester. The combination of high tensile stress (from residual welding stresses) and corrosion potential in a critical range is a prerequisite for caustic SCC. Since the early 1980s most if not all continuous digesters have been fully postweld heat treated, even though stress relief was not mandated by the ASME Code for wall thicknesses less than 32 mm (1.25 in.). Carbon steel welds and weld buildup made in the impregnation zone of digester vessels and not subsequently stress relieved are susceptible to caustic SCC. Below the cooking screens, caustic SCC has not been reported.

Until the late 1980s corrosion thinning was not a serious problem with continuous digesters, except in unusual cases where corrosive wood species such as western red cedar were being pulped. Earlier research had identified wood extractives such as catechols as very corrosive to steel under conditions of alkaline pulping (Ref 42). In more recent years there have been many cases of rapid thinning at rates approaching 6 mm/yr (250 mils/yr) of carbon steel continuous digesters, around and below the extraction screens and in the wash zone (Ref 43). High corrosion rates observed in conjunction with new pulping technologies such as EMCC and ITC are believed to be caused by a combination of higher temperatures and low hydroxide concentration that contributes to a loss of passivation of carbon steel (Ref 13, 44).

Many digesters have experienced extensive metal loss from cleaning with hydrochloric acid (HCl). Even when properly inhibited, corrosion damage (usually in the form of pitting) can occur if the temperature is above 70 °C (160 °F), which is often the case. Acid cleaning done at ≤50 °C (≤120 °F) is not considered to be corrosive. Pitting of the carbon steel wall in the

impregnation zone is usually a sign of acid cleaning damage, as continuous digesters do not usually experience corrosion thinning or pitting in this area. Alternative acids for cleaning, such as sulfamic acid and formic acid, are less corrosive to digesters (Ref 45).

Preferential weld corrosion is often observed in continuous digesters and is the result of the poorer corrosion resistance of weld metal (which has a coarse-grain structure similar to a casting), compared with the parent metal plate (which is typically lower in silicon content). The common practice of restoring corroded weld seams without subsequent stress relief results in welds with high residual stresses that may make the digester more susceptible to caustic SCC.

Stainless steels in digester vessels can experience corrosion as a result of HCl cleaning, which preferentially attacks the ferrite phase in welds, but can also cause widespread pitting if the temperature is high enough. Attack of circumferential welds in type 304L central pipes has resulted in central pipe failures. The welds often have incomplete penetration, which contributes to failure. Stainless steel top and bottom dome liners may experience SCC or intergranular attack (IGA) if they are heat treated with the digester. This practice can result in sensitization through chromium carbide precipitation at the grain boundaries. Continuous digester vessels constructed from roll-clad austenitic stainless steel can also undergo IGA if they become sensitized during postweld heat treatment, which is mandatory for the carbon steel digester shell (Ref 46).

Protection of Continuous Digesters

As corrosion rates have been observed to increase, protective measures such as corrosion-resistant weld overlay, thermal spray coating, and anodic protection have been increasingly employed. Measures such as anodic protection, taken to prevent corrosion by the pulping liquor, will not protect the digester from acid damage because the anodic protection system must be turned off during acid cleaning.

As with batch digesters, carbon steel weld buildup is not considered a permanent protective measure because it is susceptible to high corrosion rates, which can expose welding defects such as porosity. It is also susceptible to caustic SCC if in the impregnation zone.

Stainless steel weld overlays are being increasingly used in continuous digesters for protection of the carbon steel shell from corrosion thinning. The overlay properties in continuous digesters are essentially the same as those discussed in the section on stainless steel weld overlay of batch digesters. Service experience and corrosion testing (Ref 13, 16, 47) have shown that type 309 stainless steel weld overlays (applied by either the SAW or GMAW processes) have good corrosion resistance, even under nonconventional cooking operation. Indeed, the 18% minimum Cr level recommended in the TAPPI guidelines (Ref 28)

is likely adequate for good corrosion resistance. A minimum of 20% Cr is recommended for aggressive continuous digester environments (Ref 13).

Since continuous digesters are so large, it is often not practical to overlay large areas in one shutdown, so overlay is typically done over a period of years. For digesters thinned to near minimum, stainless steel weld overlay of digester walls is sometimes done in combination with anodic protection.

Preferential corrosion or “fingernailing” is often seen in the carbon steel adjacent to stainless steel weld overlay, most often in the impregnation and cooking zones. While fingernailing resembles galvanic corrosion, it is simply the preferential corrosion of the HAZ in the carbon steel, which has poorer corrosion resistance than the parent metal. Caustic SCC often begins at the bottom of a fingernailing crevice.

Protection of carbon steel weld seams susceptible to caustic SCC (in the impregnation zone) with stainless weld overlay bands has not been successful. The residual tensile stresses in the carbon steel at the termination of the overlay are high enough to promote caustic SCC (Ref 48, 49). However, anodic protection can prevent caustic SCC in these HAZs adjacent to the overlay.

Alloy 625 (ERNiCrMo3) and alloy 82 (ERNiCr3) nickel-base weld overlays have good corrosion resistance in continuous digester liquors and were widely used in the 1980s. However, most overlay being applied in continuous digesters today (2006) is type 309 stainless steel.

Thermal spray coatings, both TWAS and HVOF, have been applied in continuous digesters to protect large areas just above or below the extraction screens from corrosion thinning. Because thermal sprays do not produce a HAZ, they can also protect weld seams in the impregnation zone from caustic SCC. The thermal spray coatings applied in continuous digesters are the same as those applied in batch digesters, that is, predominantly alloy 625 and similar nickel-base alloys.

Although laboratory testing has indicated thermal spray coatings can protect against both caustic SCC (Ref 32) and thinning (Ref 50), service experience has been mixed. With good surface preparation, coatings adhere well and provide several years of corrosion protection. However, there have been problems with blistering and disbonding.

Anodic Protection. Since the early 1980s anodic protection has been successfully used to protect partially stress-relieved continuous digesters from both caustic SCC and corrosion thinning (Ref 51–57). Anodic protection of continuous digesters requires multiple external rectifiers and internal cathodes. There are two main cathode designs: centrally mounted (on standoffs from the central pipe) and wall-mounted. Anodic protection for thinning can reduce corrosion rates, but may not necessarily reduce them to zero. Anodic protection can,

however, extend the life of the corrosion allowance so that more permanent protective measures (such as stainless steel weld overlay) can be carried out later.

Ancillary Equipment

Stainless steels have been used as materials of construction for much of the equipment ancillary to digesters. This includes piping, valves, and pumps. Some of the major ancillary equipment is discussed in this section.

Liquor Heaters. External heat exchangers are used for indirect heating of the digester, most of which today (2006) are a two-pass shell and tube construction (Fig. 4). Batch digesters usually have one heat exchanger, while Kamyr units usually have three (see Fig. 3). With the continuous cook, two exchangers are in service while the third is being cleaned or in a standby mode. Tubing is 25 to 37 mm (1 to 1.5 in.) in outer diameter (OD), and from 3 to 4.6 m (10 to 15 ft) in length. Cooking liquor circulates

through the tubes, with saturated steam on the shell side. Shell side temperature is approximately 200 °C (390 °F), while the liquor is 150 to 170 °C (300 to 340 °F).

For many years, welded type 304L stainless steel tubes have been the “standard” material of construction in liquor heaters. Unfortunately, austenitic stainless steels types 304L and 316L are susceptible to both chloride and caustic SCC, which has caused many tube failures. Stress-corrosion cracking of liquor heater tubes can occur from either the steam side or the liquor side (Ref 58). Inadvertent introduction of superheated steam has caused rapid SCC of type 304 tubing. Type 304L stainless steel tubes are also susceptible to rapid liquor-side thinning, which eventually leads to tube rupture. Thinning in batch digester liquor heaters is believed to be due to high-temperature operation. In continuous digester liquor heaters, thinning may be due to HCl cleaning. Hydrochloric acid cleaning is detrimental to the welds in type 304L stainless steel welded tubing, unless the manufacturer of the welded tubing has processed the tubing to reduce the normal ferritic content of the welds.

Type 304L tubes are normally used for new construction—where cost often controls material selection—and they are replaced when SCC or thinning causes unacceptable amounts of downtime. Duplex stainless steels such as 3RE60 (S31500), alloy 2205 (S32205), and alloy 2507 (S32750) are resistant to SCC in liquor heater service but are also susceptible to thinning, especially at higher temperatures. High-nickel alloys such as alloy 600 (N06600) and alloy 800 (N08800) are resistant to SCC and have improved resistance to acid cleaning damage.

Chip conveyors, which bring chips from the wood yard to the chip feeders, use type 304 for bends and other components subject to chip abrasion. Chip feeders for continuous digesters are typically made from centrifugally cast, precipitation-hardened stainless steel alloy CB-7Cu-1 (J92180), in the solution annealed and aged (H925) condition, for best abrasion resistance. Rotors are manufactured from cast martensitic alloy CA-6NM (J91540) or from alloy CB-6 (J91804). Rotors are quenched and tempered to 240 to 302 HB. Modified versions of alloy CA-6NM have been used to enhance weldability. Rotor cracking problems have been experienced and have been largely due to casting shrinkage. Manufacturers and users have begun to specify radiographic testing of rotors to ensure quality of the casting. Worn rotors are typically rebuilt by welding with modified type 410 (S41000) stainless steel applied by the submerged arc welding method. Corrosion of carbon steel feeder housings beneath the liner is a common problem and can result in cracking of the liner. Significant corrosion must be repaired by removal of the liner and welding a stainless steel overlay onto the housing. This is then precision machined to accept the liner.

Steaming Vessels. Chips are usually pre-steamed in a steaming vessel prior to introduction into the cooking vessel through a rotary-type

high-pressure feeder. The steaming vessel is a horizontal cylindrical vessel that has conventionally been constructed from carbon steel with a partial cladding of type 304L stainless steel on the inside. A wear plate of type 304L or type 316L stainless steel is usually installed along the bottom of the vessel to protect the carbon steel wall from wear by the chips as they pass through the vessel. The wear plate usually corrodes rapidly and needs to be replaced every few years. The steaming nozzles, if constructed from type 304L or type 316L, may also experience SCC from the inside.

In the 1980s several steaming vessels were constructed from solid type 304L stainless steel. Most of these vessels experienced external SCC beneath the insulation when the insulation became wet from liquor spills. These vessels also had internal SCC in the steaming nozzles.

Duplex stainless steels such as alloy 2304 (S32304) and alloy 2205 have superior resistance to SCC and wear and are preferred for the internal lining, particularly the wear plate. Some steaming vessels have been constructed from clad duplex stainless steel (roll-clad or explosion clad) and are relatively maintenance-free.

Flash Tanks, Blow Tanks, Valves, and Pumps. In a continuous digester there are typically two flash tanks for the liquor extracted from the digester. The flash tanks were typically made from carbon steel, but there have been many reports of severe corrosion or erosion-corrosion of these vessels. High rates of flash tank corrosion usually occur when the digester is also experiencing rapid corrosion thinning. Types 304L and 316L were rated as marginal and duplex alloy 2205 is preferred (Ref 59). Corrosion was attributed to the presence of organic acids in the flash tank environment.

Thermal spray coating or lining with type 304L stainless steel has extended the life of corroding flash tanks. Replacement of flash tanks with solid duplex alloy 2205 is a solution to the corrosion problem.

The blow tank for batch digesters may be of carbon steel, type 304L, or for larger tanks, alloy 2205 construction. Blow valves are usually CF-3 (J92500) cast stainless steel. Cast duplex stainless steels such as CD-4MCuN (J93372) or CD-6MN (J93371) are preferred for pumps due to abrasion from sand and grit loadings.

Fig. 4 Digester liquor heater

Corrosion Control in High-Yield Mechanical Pulping

Chris Thompson, Paprican

High-yield mechanical pulping is the generic name for producing pulps mechanically using either disk refiners or grindstones (also

called “pulpstones”). Today (2006), high-yield mechanical pulping is dominated by disk refiner technology and, in North America, stone groundwood technology is rapidly disappearing from the scene. Newsprint and groundwood specialties typically contain high amounts of refiner pulps, sometimes as much as 100%.

A large number of refiner pulping processes have been developed, primarily as a result of the need to produce tailor-made pulps and to decrease energy requirements. The simplest process is refiner mechanical pulping (RMP), in which the chips are refined at atmospheric pressure with no prior use of heat or chemical action. For newsprint production, the dominant methods of refiner pulping are thermomechanical pulping (TMP), in which the chips are softened by heating in a steaming tube before entry into the primary refiner, and chemi-thermomechanical pulping (CTMP), in which the chips are also impregnated with a cooking chemical such as sodium sulfite. In both TMP and CTMP systems, chip steaming and refining take place at temperatures above 100 °C (212 °F), so that the steaming vessel and the first-stage refiner are pressurized. In the secondary refiner, the pulp is usually discharged at atmospheric pressure. The distinction between TMP and CTMP can be blurred, as TMP facilities sometimes add sulfite solution to the chips before refining. A schematic of a TMP system is shown in Fig. 5.

Materials of Construction and Corrosion Problems

Modern refiners are large and powerful, with disk diameters up to 1.8 m (70 in.) and motor powers of 11 MW (15,000 hp) and higher. In

operation, pulping is achieved by passing wood chips between two or more closely spaced sets of serrated refiner plates, at least one set of which is rotating. Each set of plates is assembled by bolting individual plates onto a backing disk. Refiner plates are made from abrasion-resistant white cast irons, such as 25% Cr, Ni-HiCr type D (ASTM specification A 532) or high-carbon cast stainless steels, and are treated as consumables. For more information on the wear and corrosion of refiner plates, see Ref 59.

Relatively little information exists in the literature regarding corrosion in high-yield pulping environments. A recent review is given in Ref 60. A survey of materials problems and inspection procedures for refiner systems is reported in Ref 61. A nagging concern is stress-corrosion cracking (SCC) and corrosion fatigue, particularly with regard to pressurized steaming tubes, refiner disks, and refiner drive shafts. Many of the most severe problems reported to date have occurred in coastal mills, where high chloride levels have been encountered. However, chlorides are often a problem for inland mills as well. Chlorides can be introduced from deicing salts spilled on wood in the yard. Caustic used in the mill often contains chlorides. Even if chlorides are low, they can concentrate in crevices, under deposits, and just above the waterline in the vapor phase (Ref 60). Mills reducing their freshwater usage can also be vulnerable to unexpected attack, as contaminated white water from the paper mill may be fed back to the mechanical pulp mill. The combination of the presence of chloride ions, the use of chemical pulping or bleaching agents, and the release of volatile wood acids can result in the localized buildup of highly aggressive conditions, even when nominal white-water

conditions are considered to be relatively innocuous. In some of the cases mentioned in Ref 60, corrosion was initiated under deposits or in dead zones where the local environment was considerably more aggressive than the nominal environment. For example, deposit analyses from a coastal presteaming vessel showed pH values of 1.9 and chloride levels of about 13,000 ppm (compared to a nominal chloride level in the TMP white water of about 200 ppm). One mill has reported replacement of two alloy 904L (N08904) steaming vessels with alloy C-276 (N10276) and alloy C-22 (N06022), due to serious chloride SCC of 904L, an alloy that is normally resistant to chloride SCC (Ref 62).

Type 316L (S31603) is the standard alloy used by manufacturers for the major components of refiner systems (Ref 60). Exceptions are where high strength is required (e.g., for drive shafts and refiner backing disks) and in areas where corrosion is considered to be a particular concern. Upgrading to alloy 904L or alloy 2205 (S32205) has been suggested for high chloride environments. Alloys C-276 and C-22 have been used for particularly aggressive and acidic conditions in steaming tubes. For cavitation resistance, alloy 2205 clad plate has been suggested for some applications. The metallurgy used for refiner backing disks, drive shafts, and casings varies with the manufacturer and specific process conditions. Alloys that have been used include forged 15-5PH (S15500), CA6-NM (J91540), and CB-6 (J91804). Refiner casing alloys include 316L, 904L, CA-15 (J91150), CA6-NM, and 2205 clad carbon steel. The exact choice depends on the anticipated service conditions. Chloride SCC is reported to be such a serious problem that the use of type 316L for pressurized components has been discontinued (Ref 62). Chloride SCC of CB-6 refiner cases in less than two years has also been reported (Ref 62). Driveshafts are not designed to be exposed to the process and have typically been made from alloy steels such as 4140 or 4340; some use of martensitic stainless steel and the duplex stainless steel 2507 (S32750) has been reported.

Once the principal method for producing chemical pulp, the sulfite process has lost ground to the kraft, mechanical, and semichemical pulping methods. Nevertheless, sulfite pulping remains an important process. Many similarities can be seen between kraft and sulfite mills, although chemistries are quite different. Each has batch or continuous

Fig. 5 Flow diagram of a thermomechanical pulping mill

Corrosion in the Sulfite Process

Max D. Moskal, Mechanical and Materials Engineering

Once the principal method for producing chemical pulp, the sulfite process has lost ground to the kraft, mechanical, and semichemical pulping methods. Nevertheless, sulfite pulping remains an important process.

Many similarities can be seen between kraft and sulfite mills, although chemistries are quite different. Each has batch or continuous

digestion, and some sulfite operations have chemical recovery. Following digestion, processes for washing, bleaching, and papermaking can be identical. Consequently, the following discussion is limited to liquor preparation, digestion, and chemical recovery. Figure 6 is a flow diagram of a typical magnesium-base pulping and recovery operation.

The Environment

Sulfite cooking liquor consists of free sulfur dioxide dissolved in water together with sulfur dioxide (SO_2) in the form of bisulfite. Until about 1950, sulfite pulping was an acid process using calcium as the base. Because the acid process was limited to only certain wood species, other base materials were introduced. These soluble bases are sodium, magnesium, and ammonium, and their use has broadened sulfite pulping for all wood species. Subsequent to the introduction and application of magnesium and sodium bases, several two-stage sulfite pulping methods using these bases had been developed and utilized commercially. These methods are generally characterized by a dramatic change in cooking pH between the initial stage (for penetration and sulfonation) and the second stage (for dissolution and removal of the lignin) (Ref 63).

Depending on the process, the pH of the cooking liquor can range from acid to neutral to alkaline. In acid bisulfite pulping, any pH within the range of 1.5 to 4.0 can be achieved by controlling the ratio of free and combined SO_2 . True

bisulfite pulping, with equal amounts of free and combined SO_2 , would be carried out at a pH of 4.0 to 5.0. Another important sulfite pulping process is neutral sulfite semichemical pulping, which is described in the next major section of this article.

Sulfuric acid is the principal aggressor in an acid sulfite mill. It can be generated in any number of unit operations. The environment usually contains chlorides that are often present in other chemicals used and are always present in logs that have been floated to coastal mills. Chlorides increase the aggressiveness of sulfuric acid.

Construction Materials

It can be said that stainless steels and sulfite pulping grew up together. In fact, many new alloys were tested in acid sulfite mills. Type 316 (S31600) stainless steel became the principal material of construction for sulfite mills, although more highly alloyed materials are required in a number of applications. Type 317L (S31703) and the higher molybdenum stainless steels are finding wider application, especially in the higher chloride environments. More recently, duplex stainless steels have been specified, due to their excellent resistance to pitting and stress-corrosion cracking. There are also a number of applications where specialty alloys such as alloy 20 (N08020), 6% Mo superaustenitic alloys, G-30 (N06030), and C-276 (N10276) are advantageous.

Sulfur Dioxide Production

The principal method for producing SO_2 is the burning of elemental sulfur, although some Canadian mills roast iron pyrites. The steps for preparing a sulfite cooking liquor are:

1. Burning of sulfur
2. Rapid cooling (to prevent sulfur trioxide formation)
3. Absorption of sulfur dioxide in a weak alkaline solution
4. Fortifying the raw acid

Mild steel is satisfactory for sulfur burners and combustion chambers (Ref 64). This is not a good environment for austenitic stainless steels because of the formation of low-melting-point nickel sulfide scale.

The hot SO_2 is cooled rapidly in either heat exchangers or direct-contact water spray towers. The heat exchangers, or pond coolers, are lead-lined steel pipe. Cooling towers are commonly acid-brick lined, but are occasionally constructed of 316L stainless steel. When stainless steel is used, walls should receive a constant supply of wash water. Figure 7 shows one design for a SO_2 cooler. In this case, the first section is lead or acid-brick lined, and the second section is stainless steel. Emergency water is available in case there is an excursion in temperature.

Piping from the cooling tower to the absorption tower can be exposed to sulfuric acid. Piping has been made from 316L or 317L stainless steel, although some mills use fiberglass-reinforced plastic (FRP).

The SO_2 compressors can be lined with lead or rubber, or more commonly 316L or 317L. Sometimes a more acid-resistant, copper alloy (alloy 20) stainless steel would be preferred (Ref 65).

The SO_2 fans and compressors can be lined with lead or rubber, or more commonly, with 316L or 317L construction. A better choice

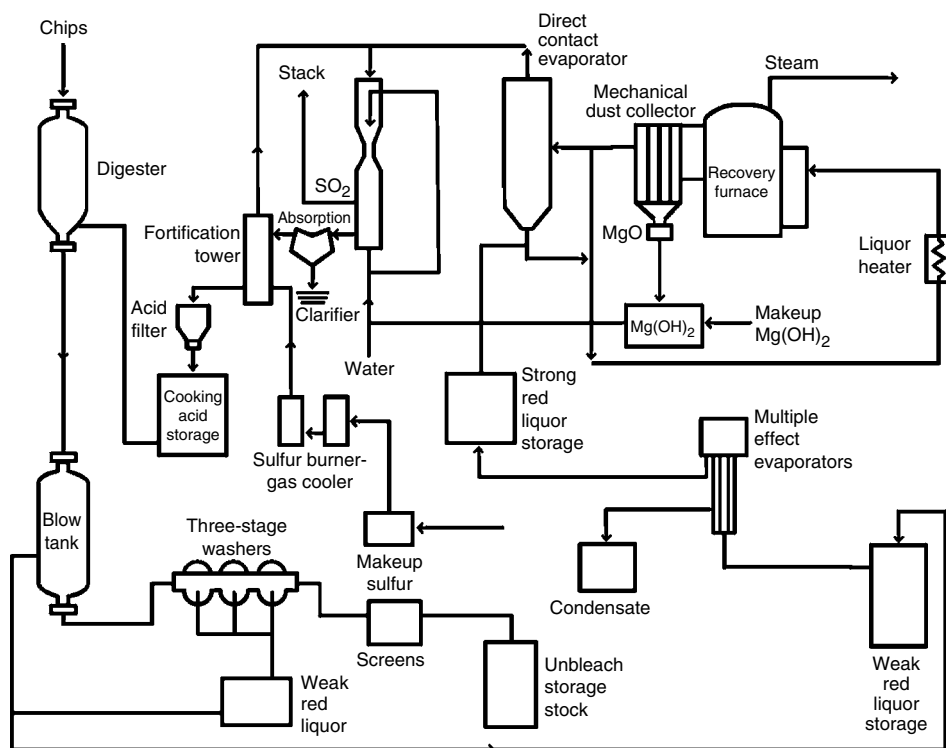

Fig. 6 Flow diagram of a magnesium-base (sulfite) mill and recovery system

Fig. 7 Spray-type sulfur dioxide cooler

would be alloys 20 or 904L (N08904), as this equipment is prone to accumulation of carryover sulfur and attack by the small amounts of sulfuric acid that are inadvertently formed in the burner (Ref 65).

Atmospheric absorption towers can be 316L or 317L or FRP. With FRP construction, all internals would be 316L or 317L stainless. Both the body and internals of pressure towers can be of stainless steel construction.

Acid tanks are usually acid-brick-lined, although 316L and 2205 (S32205) duplex stainless steel have been used. However, sulfuric acid can be present, and if the temperature exceeds 85 °C (185 °F), acid-brick-lined tanks are preferred.

Digesters

Older batch digesters were acid-brick-lined. However, digesters have more recently been constructed from 317L, 904L, 317LMN (S31726), and 2205 duplex stainless steels. Duplex stainless steel alloys offer better protection against chloride stress-corrosion cracking compared to austenitic stainless steels. In brick-lined digesters, most fittings, screens, sleeves, and man-way hatches are 316L or 317L stainless steel.

Continuous digesters for sulfite pulping are very similar to kraft continuous digesters in design. For the sulfite process, continuous digesters are all stainless steel construction using 316L (with a minimum of 2.75% Mo) or 317L (Ref 66). Duplex stainless steel has also been used in several continuous digesters.

Washing and Screening

Pumps, piping, screens, knotters, washers, and deckers may all be exposed to small amounts of bisulfite in the spent liquor, so stainless steel construction is still necessary for corrosion protection. Type 316L stainless is almost standard. However, crevice corrosion may occur under pulp deposits; so the choice may be for 317L, 2205 duplex or higher alloyed materials.

A number of sulfite mills operate liquor recovery systems. However, there appears to be considerable variation in operating conditions. Sulfite recovery boilers are primarily of carbon steel construction, with significant corrosion allowances in critical areas such as screens, superheaters, and waterwall tubes. More recent construction has incorporated composite 304L with SA210 steel tubes in the lower furnace waterwalls. Carbon steel remains the choice for floor tubes. The SO₂ content of sulfite recovery flue gas is much higher than in kraft systems, increasing the potential for sulfur trioxide (SO₃) formation.

Scrubbing systems are usually of FRP and/or 316L/317L stainless steel. Where high levels of chlorides and/or SO₃ are present, high-molybdenum stainless steels or nickel-base

alloys give better service (Ref 65). The magnesium sulfite operation presents a special case in scrubber corrosion, where the magnesium oxide (MgO) slurry in water is combined with hot SO₂ gas. In this case, the SO₂ gas enters the top of one leg of the scrubber and is combined with the MgO slurry shower. Problems of severe stress-corrosion cracking and crevice corrosion under wet salt have occurred in 317L stainless steel scrubber walls. One solution has been to replace the affected components with Ni-Cr-Mo-W (e.g., C-276) alloys. Consideration could be given to the use of duplex stainless steels in this application given the excellent resistance to pitting and stress-corrosion cracking of these alloys.

Jonsson reported that a steel corresponding to type 316L is suitable material for all components in the evaporators such as tubes, vapor bodies, liquid flash tanks, vapor pipes, condenser pipes, liquor pipes, valves, pumps, and condensers where calcium bisulfite is evaporated (Ref 65). For evaporation of magnesium-base cooking liquor, 316L with 2.75% Mo or 317L is often prescribed, since the corrosive conditions are considered to be somewhat more severe than for calcium bisulfite. For sodium-base cooking liquor, the conditions are not so corrosive, and therefore 316L is used for the first effect and 304L or mild steel for the weak liquor effects in the evaporator train. Carbon steels in the weak liquor stages have sometimes been replaced by stainless steels, primarily to reduce fouling and secondarily to reduce corrosion. The corrosion problems are less severe for ammonium-base cooking liquor.

Chloride Control

Chloride ions entering the pulp mill cycle from saltwater wood storage can cause serious corrosion of stainless steel equipment throughout the liquor cycle. A control system conceived for the MgO recovery process can greatly reduce corrosion by maintaining a low chloride ion level. The system is based on the knowledge that the chlorides leave the recovery boiler as hydrochloric acid and can be readily removed from the flue gas by a venturi absorber (Ref 67).

Corrosion Control in Neutral Sulfite Semichemical Pulping

Chris Thompson, Paprican

In neutral sulfite semichemical (NSSC) pulping, hardwood chips are cooked in a liquor solution consisting of sodium sulfite (Na₂SO₃) with a small quantity of sodium carbonate (Na₂CO₃), sodium bicarbonate (NaHCO₃), or

sodium hydroxide (NaOH). A typical strong liquor contains 120 to 200 g/L of Na₂SO₃ and 30 to 50 g/L of Na₂CO₃. The liquor is generally prepared by burning sulfur to form sulfur dioxide (SO₂), and then absorbing the gas in a solution of Na₂CO₃ (soda ash), although small mills may purchase chemicals if readily available from a nearby source.

Cooking is done in digesters similar to those used in the kraft process, except that the continuous digesters are of a different design. Typical continuous digesters include horizontal multiple-tube units or inclined-tube digesters. The cooking occurs in either the liquid or the vapor phase. For vapor-phase cooking, the chips must pass through a press impregnator before entering the digester. Figure 8 is a flow diagram for a typical NSSC mill (Ref 68). Cooking temperatures range from approximately 180 to 195 °C (355 to 380 °F) and the pH range is from 7.2 to 9. Heating is either directly by steam injection or indirectly with an external heat exchanger.

A number of mills are combined kraft/NSSC operations because both are used in the manufacture of corrugated cardboard. Consequently, the sulfur and soda obtained from NSSC spent cooking liquors are introduced into the kraft chemical recovery system to replace the salt cake lost in the kraft mill. During carbonation of the smelt, hydrogen sulfide is released. This is burned to SO₂ in a separate reactor or in the oxidation zone of the recovery boiler.

Materials of Construction

Because NSSC spent liquors are more corrosive than kraft liquors, stainless steels are generally used in all equipment. While type 304 (S30400) has been used successfully, type 316 (S31600) is generally preferred because of its better resistance to corrosion. When welding is involved, the low-carbon variations, types 304L (S30403) and 316L (S31603), are used to prevent problems with intergranular corrosion. While NSSC pulp can be bleached, using chlorine, caustic soda, or hypochlorite, bleaching is not usually required.

In a related process, pulping is done at more acidic pH levels, using bisulfite rather than sulfite as the active chemical. In some instances, this has caused rapid attack of the vapor-phase region of the digester, due to the formation of sulfuric acid vapor (Ref 69). The conditions that promote the formation of acid vapors are the presence of air and a low cooking liquor pH. Digesters for use in semichemical bisulfite pulping have been made from a range of materials, including carbon steel and austenitic stainless steels. The accelerated corrosion of a type 317L (S31703) continuous bisulfite semichemical digester has been described by Murarka (Ref 69). Formation of acid vapors was minimized by raising the liquor pH from 4 to 6 and by using a plug screw feeder to reduce the entry of oxygen with the incoming chips. Additional precautions taken were feeding

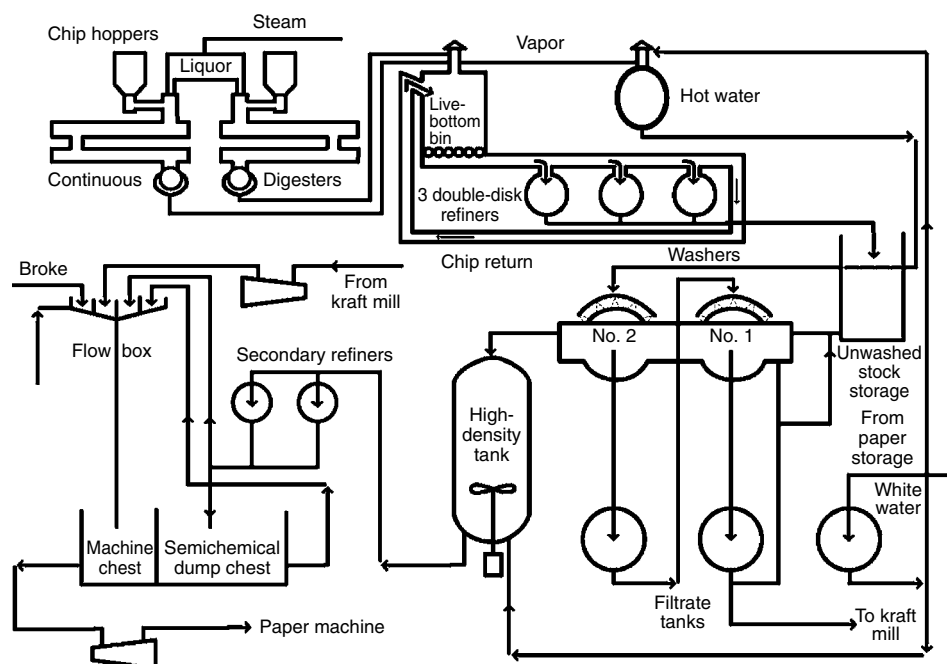

Fig. 8 Flow diagram of a typical neutral sulfite semichemical mill

the chips into the digester below the liquor level, and preheating the water in the blow tank to lower its dissolved oxygen content. The vapor space of the digester was clad in alloy 904L (N08904) stainless steel. Presteaming the chips and replacing the air in the digester with steam prior to startup have also been advocated to minimize the possibility of acidic corrosion (Ref 59, 70).

Corrosion Control in Bleach Plants

Donald E. Bardsley and William Miller, Sulzer Process Pumps Inc.

The oxygen delignification and bleach plant sequence is a continuation of lignin removal following the digester cooking process described in the section "Corrosion of Digesters." This section describes the various stages of chlorine-based and nonchlorine bleaching, process water reuse for elemental chlorine-free and non-chlorine bleaching stages, selection of material for bleaching equipment, recent developments in oxygen bleaching, and the use of more highly corrosion-resistant materials for bleach plant equipment.

Stages of Chlorine-Based Bleaching

Bleaching takes place in the oxygen delignification and bleach plant sequences in 3 to 5

steps, each step referred to as a stage (refer to Table 1 for bleach stage nomenclature). Each stage comprises four basic equipment components:

- A pump to move the pulp through the stage at the desired consistency
- A mixer to blend the pulp, chemicals, and steam
- A reaction tower or vessel (atmospheric or pressurized) with dilution and agitation equipment for discharge consistency control
- A washer to separate residual chemicals and reaction by-products from the pulp

These four components are shown in Fig. 9(a) for an atmospheric bleaching stage (Cl_2 , ClO_2 , E_0) and in Fig. 9(b) for a pressurized stage (O_2 , O_3 , P_0). The upflow section of the atmospheric stage can also be pressurized (E_0 , E_{0p} , P_{HT}). These stages are divided into two process categories within each bleaching sequence: delignification and brightening. There are a large number of different bleaching stages used in various combinations.

Delignification. Immediately following the cooking process, the delignification stages selectively continue the bulk removal of lignin from the fiber. Inclusive in this group of bleaching stages are oxygen delignification (O), chlorination (C) or chlorine dioxide (D) stages, and oxidative extraction (E_0) or peroxide-reinforced extraction stages (E_{0p}). In a bleaching sequence the delignification stages are typically grouped as D_cE_0 , D_0E_{0p} , and OD_0E_{0p} .

Brightening. Following the delignification stages are the brightening stages. These stages are most effective when the lignin level in the pulp has been reduced to less than 1% by weight.

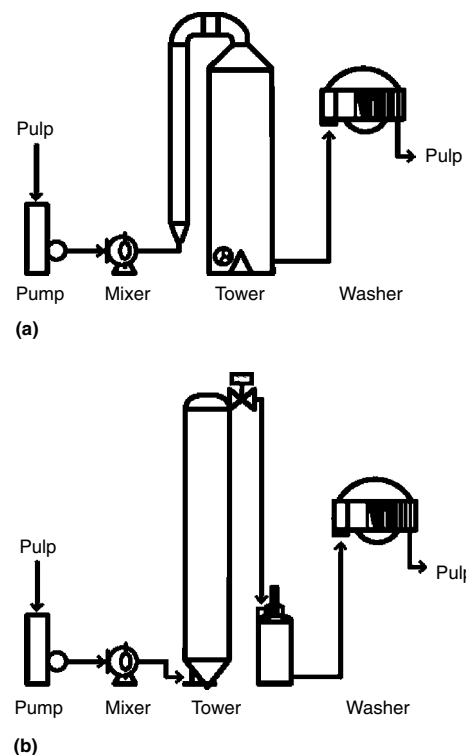

Fig. 9 Bleaching stage components. (a) Atmospheric (upflow/downflow). (b) Pressurized (upflow)

Table 1 Bleach stage nomenclature

Symbol	Process/processing chemical
C	Chlorine (Cl_2)
D	Chlorine dioxide (ClO_2)
D_0	Full chlorine dioxide substitution for chlorine
D_c	Partial chlorine dioxide substitution for chlorine
D_n	Neutralized with caustic
E	Caustic extraction
E_0	Oxidative caustic extraction
E_{0p}	Peroxide/oxygen caustic extraction
H	Hypochlorite
O	Oxygen (O_2)
Z	Ozone (O_3)
P	Peroxide (H_2O_2)
P_{HT} or P_0	Peroxide, hot or pressurized

Permanent brightness development occurs as this remaining lignin is removed or modified in the brightening stages. These are typically chlorine dioxide stages (D), with intermediate caustic neutralization steps (D_n), or mild caustic extraction stages (E). In a bleaching sequence, the brightening stages are typically grouped as D, DED, DD, or D_nD .

Bleaching Sequences. The final International Organization for Standardization (ISO) brightness target and environmental constraints define the combination of delignification and brightening stages in a bleach plant design. The most typical sequences are:

- $\text{D}_c\text{E}_0\text{D}_n\text{D}$ to achieve 88 to 90% target brightness
- ODE_{0p}D to achieve 85 to 88% target brightness

These sequences were selected to encompass the scope of bleach stage design parameters currently utilized in bleach plants. The $ODE_{op}D$ sequence, with no elemental chlorine used, is referred to as an elemental chlorine-free (ECF) sequence. Figure 10 schematically outlines the $D_cE_oD_nD$ bleaching sequence.

Table 2 summarizes the typical operating and design parameters for $D_cE_oD_nD$ and $ODE_{op}D$ sequences to achieve 88 to 90% and 85 to 88% ISO target brightness, respectively, on softwood pulp. The O_2 delignification stage in the $ODE_{op}D$ sequence is designed to reduce the brown stock kappa number to 18. The kappa number measures the amount of lignin present in a kraft pulp:

$$\text{kappa number} \times 0.15\% = \% \text{ lignin in pulp}$$

For example, if the kappa number of a conventionally cooked pulp after O_2 delignification is 18, this kappa number corresponds to a lignin content of 2.7%.

Nonchlorine Bleaching Stages

Nonchlorine bleaching stages, utilized in both the delignification and brightening stages of a bleaching sequence, are designed to reduce or eliminate the use of chlorine-based (ClO_2) bleaching chemicals. These stages are the building blocks for the totally chlorine-free (TCF) bleaching sequences.

Delignification. The function of the delignification stages is identical to those described in "Stages of Chlorine-Based Bleaching." Inclusive in this category for nonchlorine bleaching stages, the bleaching stages utilized are oxygen delignification (O), ozone (Z), and pressurized hydrogen peroxide reinforced, oxidative extraction stages (E_{op}).

Brightening. Following the delignification stages are the brightening stages, as previously described. For nonchlorine bleaching the brightening stages are typically pressurized, oxidative hydrogen peroxide stages (P_{HT} , P_O , P).

Bleaching Sequences. Nonchlorine bleaching stages in ECF sequences are used primarily to maintain final brightness targets while lowering active chlorine demand. The nonchlorine stages can be utilized to reduce active chlorine in both the delignification and brightening stages.

The final brightness target and environmental constraints define the combination of nonchlorine delignification and brightening stages in an ECF bleach plant design. For example purposes only, a proposed $D_0(ZE_{op})DP_{HT}$ bleaching sequence is shown schematically in Fig. 11. The purpose of this figure is to illustrate how a plant might apply an ozone (Z) delignification stage and/or a P_{HT} brightening stage.

Bleaching Stages. The range of operating conditions for nonchlorine bleaching stages are outlined in Table 3. These conditions are used to optimize the displacement of active chlorine in

the delignification and brightening stages while maintaining pulp quality.

Process Water Reuse for ECF and Nonchlorine Bleaching Stages

Many bleach plants today recycle filtrates countercurrently to accomplish at least partial closure (see Fig. 12, 13). The bleach plant

effluent, which flows to the waste treatment plant, is primarily overflow from the D_c/D_{100} and E_{op} stages.

There are several benefits to recycling filtrates, such as:

- Reduction in water consumption and effluent flow
- Reduction in chemical consumption (NaOH and H_2SO_4)
- Reduction in heating requirements

NA, not applicable; atm, atmospheric pressure. (a) Totally chlorine-free, ECF

In cases where bleach stage residual is high, filtrate recycling can also lead to corrosion in certain parts of the bleach plant.

The effluents from the bleaching operation contribute a significant portion of the chemical oxygen demand (COD), color, and absorbable organic halide (AOX) to the overall effluent stream. Environmental regulations have put limitations on the levels of these components discharged with bleach plant mill effluent. This has led to a decrease in the use of chlorine and chlorine-containing compounds and to the trend toward ECF and nonchlorine bleaching sequences. Recent bleach plant design is also focusing on reducing the effluent flows by increasing the level of filtrate recycling.

Reevaluation and increased monitoring of the construction materials used throughout the bleach plant are becoming more critical as new bleaching processes and increased filtrate recycling are utilized in bleach sequences (Ref 71).

Selection of Materials for Bleaching Equipment

Materials for bleach plant equipment have undergone major changes over the past 30 years. In the 1970s recycling of wash water and approaches to closure of the wash-water cycle increased corrosivity. Changes in bleaching processes and reduction in time available for maintenance, together with recycling of wash water, required upgrading to more highly alloyed, more corrosion-resistant materials in the late 1970s and 1980s. More recently, the need to reduce dioxins has resulted in replacing chlorine with chlorine dioxide (ECF bleaching). Substituting oxygen and hydrogen peroxide for both chlorine and chlorine dioxide, as some mills have done, is known as TCF bleaching. Totally chlorine-free bleaching requires less highly alloyed materials than ECF bleaching. Type 316L (S31603), CF-3M (J92800), and CF-8M (J92900) are quite adequate for most applications in TCF bleaching.

For environmental reasons, a number of mills have eliminated the chlorination stage. Only a few continue their use of chlorine, and these are expected to discontinue use of chlorine within the next few years. In ECF bleaching where elemental chlorine has been eliminated, the bleaching sequence normally comprises two to three chlorine dioxide stages. The use of ECF bleaching is expected to continue to grow in North American mills. Only a few mills have adopted TCF bleaching because it lacks economic appeal. The hypochlorite stage, which was very popular in the 1950s, has been largely abandoned in North America and Europe, but is still in use in South America and the Far East.

Some of the more common materials used in the older chlorine (C), chlorine dioxide (D), and hypochlorite (H) stages are shown in the first three columns of Table 4. Piping that leads to the chlorine or chlorine dioxide tower is fiberglass-reinforced plastic (FRP). The tower itself is steel with a membrane, acid-brick lining, or solid FRP. Piping from the towers is either 6% Mo stainless steel or FRP. Cast alloys CW-2M (N26455) and CX-2MW (N26022) performed well in chlorine-stage chemical mixers. In both the chlorine stage with chlorine dioxide substitution and the chlorine dioxide stage, these Ni-Cr-Mo alloys (equivalent to wrought alloys C-4 and C-22, respectively) have suffered substantial corrosion. Titanium is the preferred material for both the chemical and high shear mixers in the D stage washer. In the old C stage, precautions must be taken to prevent dry chlorine from entering the titanium mixer in order to avoid a pyrophoric reaction. Superaustenitic 6% Mo stainless steels have become standard for the C and D stage washers.

During ECF bleaching when countercurrent washing is utilized in the bleach plant, caustic filtrate is applied as shower water on the first-stage chlorine dioxide bleach dioxide filter to displace the chlorine dioxide in the pulp mat. Residual chlorine dioxide in the pulp mat combines with the caustic, resulting in the formation of sodium chlorate and sodium chlorite in:

The resulting condition is known as near-neutral chlorine dioxide with a pH of 6 to 7.

Superaustenitic, 6% Mo stainless steels have adequate resistance to near-neutral chlorine dioxide. However, the nickel-base alloy filler metals, AWS ERNiCrMo-4 (N10276) and AWS ERNiCrMo-10 (N06022), normally used for fabrication, are subject to what has been termed transpassive corrosion in this near-neutral chlorine dioxide environment. These nickel-base filler metals undergo molybdenum dissolution, which renders them unsuitable for this near-neutral chlorine dioxide environment. After some investigation, it was found that AWS ERNiCrMo-11 (N06030) with higher chromium and lower molybdenum had much better corrosion resistance in the near-neutral chlorine dioxide environment while still maintaining good resistance to acid chloride environments. ERNiCrMo-11 has become the

Fig. 11 Flow diagram of a $D_0(ZE_{op})DP_{HT}$ elemental chlorine-free bleaching sequence. The (ZE_{op}) stage in parenthesis denotes no wash between stages. In some instances, a chelation or acid-rinse step followed by a wash may be required prior to the P_{HT} and P_o stages.

preferred filler metal for fabricating 6% Mo stainless steel washers for near-neutral chlorine dioxide stage service.

For the newer, less corrosive, oxygen, peroxide, and caustic stages (shown in the remaining columns of Table 4), 316L and its cast counterpart CF-3M are the principal materials used for the towers, pumps, and mixers. For 316L towers, it is necessary to protect the outside from chloride stress-corrosion cracking (SCC) beneath the insulation, as described in this article and in the article "Corrosion Under Insulation" in this Volume. Some mills have selected duplex stainless steel for the oxygen towers because of its better resistance to chloride SCC. Zirconium is used for the high-shear mixer in the hot alkaline peroxide stage.

For bleach plant service, it is desirable that all wetted surfaces be clean and free of embedded iron and other fabrication-related defects. It is essential that type 316L hydrogen peroxide towers and other peroxide wetted surfaces are free of embedded iron, as embedded iron degrades hydrogen peroxide. ASTM A 380 and A 967 provide the guidelines for detection and removal of embedded iron and other fabrication defects using mechanical, chemical, and electrochemical methods.

Oxygen Bleaching

Oxygen has become a principal technology to replace chlorine-based chemicals for bleaching

pulp. Oxygen usage is expected to continue growing as chlorine usage declines. Initially, oxygen bleaching was done on high-consistency pulp, leaving a gas phase at the top of the vessel. Pressures were as high as 0.8 MPa (120 psig) and temperatures as high as 135 °C (275 °F), conditions that are conducive to internal chloride SCC. The interface between liquid and vapor in high consistency bleaching provided a "hot wall" effect, where chlorides could concentrate just above the liquid level, increasing the probability of internal chloride SCC.

In order to prevent internal chloride SCC of 316L when gas-phase oxygen bleaching began in the early 1970s, Scandinavian mills "cold stretched" 316L oxygen reactors. Cold stretching was achieved by overpressuring the vessel sufficiently so that, at operating pressures, the inside surface remained in compression and resistant to chloride SCC. Cold stretching also allowed a reduction in wall thickness under Scandinavian pressure vessel codes. In North America, where codes did not allow a reduction in wall thickness for cold stretching, upgrading to solid or clad alloy 20 (N08020) became the practice to resist chloride SCC in oxygen reactors.

The initial process was changed to treat medium consistency pulp in an upflow mode instead of downflow mode, eliminating the vapor space to the top of the vessel, where chlorides could concentrate and initiate chloride SCC. This reduced the potential for internal chloride SCC of 316L without the need for

cold stretching. Most of the oxygen reactors treating medium-consistency pulp in the upflow mode have been 316L. Recently, some have been fabricated from alloy 2205 (S32205), a duplex stainless steel which is resistant to chloride SCC.

Type 316L is quite susceptible to external SCC under insulation when the insulation becomes wet from rain or even high humidity. NACE Publication RP 0198 "Standard Recommended Practice—The Control of Corrosion under Thermal Insulation and Fireproofing Materials" provides the necessary information for keeping the outside surface of 316L reactors, and other 304L (S30403) and 316L vessels and towers, dry and resistant to SCC. Although internal chloride SCC has not been reported in vessels where pulp is treated with oxygen in the upflow mode with no vapor space at the top, a number of mills have elected to upgrade to alloy 2205 for better resistance to both internal and external chloride SCC. Type 316L and CF-3M are satisfactory for other components in the oxygen and hydrogen peroxide bleaching stages.

Pumps, Valves, and the Growing Use of Duplex Stainless Steels

Since conditions vary considerably from mill to mill, individual mill site experience generally provides the best guide for alloy selection and upgrading. The pitting resistance equivalent

Note: 6%Mo denotes superaustenitic stainless steels. (a) To prevent external SCC, special care of type 316 in insulation is required. (b) Heat tint and embedded iron must be removed from all wetted surfaces to reduce decomposition of hydrogen peroxide. (c) Titanium must be protected from contact with dry chlorine by interlocks to avoid pyrophoric reactions. (d) Zirconium is used for the high-temperature (>100 °C, or 212 °F), more aggressive applications.

nitrogen number (PREN) provides very useful guidelines for upgrading bleach plant materials when upgrading is necessary. The PREN is a calculated parameter used to estimate the expected resistance to localized corrosion by chlorides. For stainless steels, it is calculated from composition using the empirical formula:

$$\text{PREN} = \% \text{Cr} + 3.3 \times \% \text{Mo} + 16 \times \% \text{N}$$

where chromium, molybdenum, and nitrogen are the respective concentrations of these elements in the alloy expressed in percentages by weight. In general, the larger the numerical value of PREN is, the higher the pitting resistance will be, although a high numerical value of PREN should not be viewed as an absolute guarantee of freedom from localized attack.

The earlier practice of upgrading to 317L (S31703, PREN = 30 to 35) in North America, and to alloy 904L (N08904, PREN = 36) in Europe, when 316L (PREN = 24 to 30) proved marginal or inadequate, is being supplemented, and to an extent superseded, by the current trend of upgrading to a duplex alloy, usually alloy 2205 (PREN = 36). Alloy 2205 is becoming the preferred upgrade whenever higher strength, better resistance to chloride SCC, or better resistance to abrasion is needed. Alloy 2205 is also often the choice for large field-erected vessels, where its higher strength can be used to offset much of the higher material cost.

The cast version of 317L, CG-3M (J92999), and 6% Mo alloys, CN-3MN (J94651), and CK-3MCuN (J93254), have become standard for filtrate pumps in the chlorine and chlorine dioxide stages. CF-3M, CG-3M, and the duplex grade CD-3MN (J92205) are used for pulp stock feed pumps in these two stages. CF-3M and CG-3M and the cast duplex grades are the principal stock pump materials in the six less corrosive bleaching stages. Duplex is preferred wherever there is abrasive wear. CK-3MCuN and CN-3MN are preferred for valves in the chlorine stages. CG-3M, CG-8M (J93000), and CN-7M (N08007) are used for valves in the six less corrosive services. CN-7M is preferred for control valves.

Titanium is the only material that has been used for continuous bleaching towers, despite the considerable maintenance required.

those exposed to the white-water environment by immersion, splashing, vapor mist, or in the damp crevices beneath pulp pads or other deposits. Materials of construction susceptible to corrosion include stainless steels, carbon steel, copper alloys, and cast irons.

This section is divided into three parts. The first part describes the materials of construction of the paper machine components and the specific corrosion problems affecting them; the second part deals with the composition and corrosive nature of white water; the third part is a more detailed discussion of specific corrosion mechanisms.

Paper Machine Components

Good introductions to the corrosion problems in paper machine wet ends and dryer sections have been published by Bennett and Sharp (Ref 72, 73). Most wetted paper machine surfaces are constructed using austenitic stainless steels such as type 304L (S30403) and type 316L (S31603) (Ref 74, 75). Type 304L stainless steel was traditionally used in white waters of lower chloride content, but is not commonly used in new paper machines. Type 316L stainless steel is the standard stainless steel used in modern paper machines, particularly those where chloride ions are present in significant concentration (>100 ppm). Type 316L stainless steel contains molybdenum that confers a resistance to chloride and thiosulfate pitting and crevice corrosion. Stainless steels having even higher molybdenum contents have been used as materials of construction in particularly corrosive paper machine white waters that result from high degrees of recycled water or system closure (Ref 76, 77). Specification of a corrosion-resistant grade of stainless steel is not in itself sufficient action to ensure that the paper machine is free from corrosion. Cleaning of the stainless steel during fabrication is essential to avoid contamination of surfaces. Iron oxides, heat tint, weld spatter, and slag from welding can all impair the corrosion resistance of the underlying stainless steel. Embedded dirt or iron, from inappropriate use of carbon steel wire brushes for weld cleanup, may

provide sites for pitting to initiate on the stainless steel surfaces. It may be necessary to passivate the stainless steel surface with a nitric acid solution while in service in order to dissolve embedded iron while leaving the stainless steel intact. Pickling solutions are much more aggressive than passivating solutions, since they typically contain fluoride in addition to the nitric acid, and are used to remove both heat tint and surface iron contamination. However, pickling solutions can also dissolve the stainless steel metal surface leaving it slightly rough.

Stock Piping. Paper machine stock piping is typically thin-gage (schedule 10) type 304L or 316L austenitic stainless steel. Corrosion is generally not a problem in stock lines if the correct stainless alloy, weld filler metal, welding process, and cleaning procedure have been chosen. Corrosion problems may occur at weld joints with incomplete penetration or mismatch, where surfaces have become roughened, or where weld projections exist that provide sites for stock hang-up. Crevice corrosion or microbiologic attack is liable to occur under deposits (Ref 78). Fatigue cracking problems are often associated with welding defects such as incomplete penetration in stock piping. Great care must be taken to ensure that good quality full-penetration welds are realized. For root passes, inert gas purging is preferred over so-called antioxidation fluxes.

Headboxes may also experience internal mechanical damage (e.g., from rectifier roll failure), and there is always the possibility of stray-current damage in addition to being susceptible to corrosion damage (Ref 79). Stock hang-up on rough or corroded surfaces may result in the frequent release of pulp pads causing product quality problems or even sheet breakage. Clean, smooth, surfaces inside the headbox are essential. Pickling, passivation, and buffing with abrasives are commonly used to provide a smooth surface finish. Electropolishing improves the finish for surfaces of 0.4 μm (15 $\mu\text{in.}$) and above (Ref 80). Headboxes have typically been constructed using type 316L stainless steel, although stainless steels with higher molybdenum content such as type 317L have also been used where corrosion resistance is a concern.

Paper Machine Corrosion

Angela Wensley,
Angela Wensley Engineering

MOST OF THE CORROSION PROBLEMS IN PAPER MACHINES occur in the wet end (Fig. 14) and in ancillary equipment handling white water. Areas susceptible to corrosion are

Fig. 14 Wet end of a fourdrinier paper machine

A calcium deoxidized machinable version of type 316L stainless steel is sometimes used in headboxes because of its superior machinability and electropolishing properties. Machinable stainless steels have greater freedom from macroinclusions than do conventional grades, but the microinclusions provide more sites for initiation of pitting corrosion. Machinable stainless steels have less corrosion resistance than conventional grades of stainless steel with an equivalent molybdenum alloying content.

Headbox apron and slice lips are particularly prone to pitting corrosion attack. Corrosion pits that initiate outside the liquid flow may grow in size and eventually reach the edge where they will have a detrimental effect on sheet formation. The use of highly pitting-resistant stainless steel, such as the 6% Mo grades, has been successful in preventing pitting of slice and apron lips.

Paper Machine Wires. Before the advent of synthetic plastic mesh fabrics, paper machine wires were typically phosphor bronze screens. Bronze screens are still used on a few older machines. Bronze wire life is limited by wear and corrosion attack (Ref 81). Corrosion inhibitor additions can increase the service life of bronze wires (Ref 78, 82). Sacrificial galvanic corrosion of the wires can result when the bronze screens come in contact with a bronze couch roll, effectively providing cathodic protection to the couch roll. The change to synthetic fabrics has resulted in the loss of this "cathodic protection" to bronze couch rolls (Ref 83).

Wet-End Structures. Wet-end carbon steel structural members are typically protected by using either paint coatings or stainless steel cladding (Ref 84). Where coatings fail or where white water can gain access beneath stainless steel cladding (at incomplete seal welds or perforations), the underlying structural steel may corrode away rapidly. Industry experience with wet-end coating systems involving inorganic zinc-rich primers and epoxy-polyamide top coats has not been good. Immersion service coating systems such as organic zinc/amine adduct-cured epoxy and inhibited epoxy/amine adduct-cured epoxy systems both appear to offer a longer service life (Ref 85, 86).

Vacuum Pumps. Liquid ring vacuum pumps typically have ductile cast iron rotors and gray cast iron casings. Corrosion of the rotors and casings occurs when corrosive seal waters are used. Ideally, the seal water should be cool freshwater. Paper machine white water is considered unsuitable for use as seal water due to its high temperature and low pH. Even freshwater may become corrosive if the flow rate is so low that the temperature of the water increases inside the pump or if it becomes contaminated with white-water carryover. A discharge seal water temperature of greater than 50 °C (120 °F) and/or a pH of less than 4.5 can cause accelerated cast iron corrosion. Corrosion rates may be lowered by adding a small amount of caustic to the seal water. High-discharge seal water conductivity (in excess of 200 μ S) may indicate

excessive white water-carryover. Accelerated impeller corrosion can occur at rotor tip speeds above 27 m/s (80 ft/s) (Ref 87). The presence of sand or grit in the water will cause erosion that shortens the life of liquid ring pumps.

A residue of graphite is left behind as cast irons corrode. Pearlitic ductile iron forms a more protective graphite surface layer than ferritic ductile iron does since the three-dimensional carbonaceous residue from pearlite dissolution acts as a binder for the graphite. Rapid liquid ring vacuum pump corrosion can be expected if environmental, velocity, or erosion conditions are such that the protective graphite film is removed. Liquid ring vacuum pumps have been built using stainless-lined bodies and stainless steel rotors for service in particularly corrosive white waters.

Roll Journals. Corrosion fatigue cracking results from the combination of cyclic stresses and a corrosive environment. Corrosion fatigue cracking failures occur after fewer stress cycles and at lower stress levels than failures due to pure mechanical fatigue. Small-diameter journals for felt rolls in wet-end environments are susceptible to corrosion fatigue, particularly if the machine speed has been increased significantly from its original design speed. Corrosion fatigue cracking may also occur at abrupt changes in the section size of journals. The environment promoting corrosion fatigue may be produced by splashing white water, the formation of damp pads of pulp on the journals, or even the humid atmosphere of the machine. Felt roll journals may also be exposed to acidic felt cleaning chemicals.

Improved corrosion fatigue performance can be achieved by protecting journals from their environment, by incorporating a redesign to increase their diameter, by removing step changes in section size, and by polishing to remove surface flaws (Ref 88).

Proper materials selection can ensure better resistance to corrosion fatigue cracking. Roll journals have been constructed using medium- or high-carbon steels, low-alloy steels, cast irons, and various grades of stainless steel. Fatigue strength is generally proportional to tensile strength. The most commonly used materials for roll journals are high-strength low-alloy steels such as G41400 (SAE 4140) and G43400 (SAE 4340). Austenitic stainless steels have relatively poor corrosion fatigue resistance and are not commonly used for roll journals in wet-end environments. Duplex stainless steels such as alloy 2205 (S32205) and precipitation-hardened stainless steels such as 17-4 PH (S17400) (in condition H1100) offer better corrosion fatigue resistance than more conventional journal materials. The use of integral (one-piece) ductile cast iron roll heads and journals having a generous radius between the head and journal may also improve resistance to corrosion fatigue. No roll journal material is immune to corrosion fatigue since there is no fatigue limit below which an indefinite service life could be expected.

Wet-end roll journals can be physically protected from exposure to white water. Stainless steel shields, paint coatings, and thermal spray coatings have all been used for journal protection. The disadvantage of physical barriers is that they hinder the inspection of the roll journal surfaces for cracking. Dry-end (reel spool) journals are usually made from 4140 or 4340 low-alloy steels in the quenched-and-tempered condition. Type 4340 is often preferred for larger section sizes since it is hardened deeper.

Suction roll shells operate in a corrosion fatigue environment without a safe fatigue limit. All suction roll shells will have a finite service life regardless of the material of construction. Corrosion-related failures of suction roll shells are discussed in the section "Suction Roll Corrosion" in this article.

White Water

White water is the aqueous medium in which the cellulose fibers are suspended. White waters contain appreciable amounts of dissolved organic and inorganic compounds, some of which contribute significantly to white-water corrosivity.

Closure of papermaking systems occurs when white water is recycled instead of being discharged to the environment. Closure results in increased concentrations of dissolved inorganic and organic solids, a decrease on the pH, and an increase in temperature. All these factors are known to increase corrosivity. The degree of closure can be expressed as the volume of water consumed per ton of paper produced (Ref 89). Closed-system paper mills may discharge less than 5 m³/tonne (195 ft³/ton), whereas an open-system paper mill may discharge more than 40 m³/tonne (1560 ft³/ton).

Closure is considered detrimental for corrosion. However, there is no clear parallel between increasing closure and increasing paper machine corrosion (Ref 89, 90). Accelerated corrosion may be expected for materials that undergo general corrosion attack, such as carbon steels, cast irons, and copper alloys. Increasing closure may decrease the "margin of safety" for stainless steels. The margin of safety for a stainless steel is the difference between the pitting corrosion breakdown potential and the free corrosion potential of the stainless steel. The grades of stainless steel having higher contents of molybdenum have larger margins of safety and therefore are more resistant to pitting corrosion. The molybdenum content of modern type 316L stainless steel is often only 2.01% Mo, which is at the low end of the specified range of 2% to 3% Mo for this alloy (Ref 91). Older versions of type 316L stainless steel tended to contain molybdenum toward the higher end of this range, typically at least 2.6%. New paper machines made using modern type 316L stainless steel may be less corrosion resistant than paper machines made using the older type 316L.

Composition. Paper machine white waters can vary widely in composition. The corrosivity of white water depends primarily on such parameters as the pH, temperature, and the concentrations of inorganic anions such as chloride and thiosulfate. The inorganic compounds found in white waters come from the wood, the pulping process, bleaching or brightening processes, and the chemicals used in the wet end of the machine, such as fillers, sizing agents, retention aids, defoamers, slimicides, and dyes. Seawater absorbed by logs during ocean transport in floating rafts will result in high concentrations of chloride ions. Kraft pulping will introduce sulfates. Chemi-thermomechanical pulping may add sulfites. Chlorine dioxide and hypochlorite bleaching will introduce chloride ions. Unreacted oxidants such as chlorine dioxide can be carried over onto the paper machine with the bleached pulp. White waters may also contain decomposition products of sodium hydrosulfite used in the brightening of mechanical and thermomechanical pulps. The average composition of the white water in a West Coast newsprint mill using semibleached kraft, chemi-thermomechanical pulp, and groundwood is:

Temperature, °C (°F)	48 (118)
pH (initial)	4.6
pH (on standing)	3.0
Sodium chloride (NaCl), ppm	311
Sodium sulfate, ppm	855
Sodium thiosulfate, ppm	34
Sodium sulfite, ppm	75
Conductivity, μ S	1749

The contribution of each of the aforementioned parameters on white-water corrosivity is discussed below.

Temperature. Increased temperature due to closure contributes to energy savings and also improves drainage in the wet end of a paper machine that permits an increase in machine speed. However, higher temperatures are detrimental for corrosion. As a rule of thumb, the rates of most chemical reactions (including corrosion reactions) double for each 10 °C (18 °F) increase in temperature. Increases in corrosion rates of this magnitude probably apply to general corrosion of the carbon steels, cast irons, and copper alloys. Stainless steels have a "critical pitting temperature." Pitting corrosion of stainless steels will initiate above this temperature. This temperature is dependent on the alloy and on the chloride concentration in the white water. Stainless steels with higher molybdenum content have higher critical pitting temperatures. A higher chloride concentration lowers the critical pitting temperature.

pH. In acid papermaking the white-water pH is typically in the range from 4 to 6. The pH is controlled on the acid side by alum additions and/or by souring the white water with sulfur dioxide, sulfite, or sulfuric acid.

Below a pH of about 4 the general corrosion rates of many nonpassive metals are accelerated. This is due to hydrogen ions becoming so plentiful that the reduction of the hydrogen ion to

form hydrogen gas replaces the reduction of dissolved oxygen molecules as the predominant cathodic half reaction in the corrosion process. Under acid conditions, corrosion is no longer limited by the rate of diffusion of dissolved oxygen into the metal. This decreased pH also lowers the stability of passive films on stainless steels, making them more susceptible to the initiation of pitting. Low pH conditions also increase the probability that once a pit is initiated it will continue to grow.

If white water is left standing, as may occur during a shutdown, the white-water pH may decrease from 0.5 to 2.0 units within approximately 24 h. There are many reasons for this. One possible mechanism is the continued oxidation of hydrosulfite and bisulfite that generates free hydrogen ions.

Chlorides. Transporting logs in seawater to coastal mills may induce chloride concentrations in the process streams that are orders of magnitude higher than those found in inland mills. Since chloride ions are very soluble, they tend to persist through the pulping process and eventually end up in the white waters. Increasing chloride concentrations increase the general corrosion rate of carbon steels and may also increase the corrosion rate of copper-base alloys. Chlorides are also agents for pitting corrosion, crevice corrosion, and stress-corrosion cracking (SCC) of austenitic stainless steels. Stress-corrosion cracking of conventional austenitic stainless steels usually requires temperatures above 60 °C (140 °F). Stress-corrosion cracking increasingly becomes a problem in mills with a high degrees of closure and where white-water temperatures have crept upward.

Sulfates. Sulfate ions (SO_4^{2-}) appear in white water as a residual chemical from the kraft chemical pulping process. Sulfates can also come from seawater, alum, sulfuric acid additions, and the oxidation of other sulfur-containing ions, such as bisulfate (HSO_3^-), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), and hydrosulfite ($\text{S}_2\text{O}_4^{2-}$). Sulfate is the thermodynamically stable oxidation state of sulfur in white waters. The prolonged contact of white water with air will result in the conversion of all lower-oxidation state forms of sulfur to the stable sulfate form.

Sulfate is not an aggressive anion, and it can act as an inhibitor for chloride-related pitting. The inhibiting effect is particularly pronounced if the molar concentration of sulfate is in excess over the molar concentration of chloride ions (Ref 91, 92). On the other hand, sulfate ions make a significant contribution to the white-water conductivity. Sulfate tends to increase the rate of electrochemical corrosion reactions by facilitating charge transfer electrolyte in electrochemical corrosion reactions. Sulfate ions are also consumed by sulfate-reducing bacteria that result in microbiologically influenced corrosion (MIC) of paper machine equipment. Sulfate can also enhance thiosulfate pitting in white waters containing thiosulfate ions (Ref 93).

Thiosulfates. Mills that use hydrosulfite brightening have appreciable amounts of corro-

sive thiosulfate ions in their white waters as the result of anaerobic decomposition of warm hydrosulfite solutions during storage. Hydrosulfite is very rapidly and stoichiometrically converted to thiosulfate under nonoxidizing conditions. By contrast, the oxidation of hydrosulfite in air does not produce thiosulfate. In practice, adding hydrosulfite to meet target brightness levels serves only to introduce even more thiosulfate into the white-water system (Ref 94). The kinetics of the oxidation of thiosulfate to sulfate is so slow that appreciable thiosulfate concentrations can build up.

Thiosulfate concentrations in white water can be reduced by ensuring that the concentration in the original source is as low as possible. Hydrosulfite solutions stored at 2 to 9 °C (36 to 48 °F) and/or the addition of an alkaline stabilizer to maintain a pH of 10 or more minimizes thiosulfate formation (Ref 95). Brightening at a pH level over 5 will also help to keep thiosulfate levels down. Thiosulfate ions have been found to be particularly aggressive pitting agents for austenitic stainless steels (Ref 93, 96). Thiosulfate ions also contribute to rapid general corrosion of copper-base alloys (Ref 97, 98).

Sulfites. Sulfite additions are used in chemi-thermomechanical pulping and are also made elsewhere to control pH or to brighten stock. Bisulfite (the stable form of sulfite in white water) is also produced during the decomposition of hydrosulfite brightening solutions. Sulfites are readily oxidized to sulfate in the presence of dissolved oxygen. Sulfite is not considered to be aggressive; in fact, sulfites are often used as oxygen-scavenging inhibitors in other aqueous systems as in boiler feedwater systems. Sulfites should have inhibitive properties in paper machine white water. Very high concentrations of bisulfite (>200 ppm SO_3^{2-}) in white water may result in sulfur dioxide evolution that in turn can cause atmospheric (dew-point) corrosion problems on aluminum paper machine dryer hoods.

Conductivity. Higher conductivity is generally an indication of increased corrosivity in white waters.

Corrosion Mechanisms

Corrosion is an electrochemical process. Corrosion reactions are the net sum of anodic (oxidation) and cathodic (reduction) partial reactions. The corrosion of iron in waters of near-neutral pH is the sum of an anodic dissolution of iron and a cathodic reduction of dissolved oxygen:

The corrosion rate of iron in near-neutral waters is limited by the solubility of oxygen in water and

the rate of diffusion of dissolved oxygen to the metal surface.

The corrosion of iron in more acidic waters ($\text{pH} < 4$) produces a reduction in hydrogen ions:

The rate of the corrosion reaction in acid solutions is not diffusion limited and can proceed at a rapid rate.

Chloride Pitting and Crevice Corrosion.

Stainless steels rely on the formation of a stable passive film for immunity to corrosion in paper machine white waters. The passive film is thin, is highly resistant to dissolution, and protects the underlying stainless steel from corrosion. Oxidizing conditions must be present for the passive film to form and be maintained. Dissolved oxygen from the air is usually sufficient to maintain stable passivation. Stainless steels can withstand slightly reducing conditions in flowing white waters without suffering appreciable corrosion attack. Excessively oxidizing conditions, resulting from the presence of oxidizing agents such as chlorine dioxide, may result in the corrosion potential of the stainless steel exceeding its breakdown potential resulting in a localized breakdown of the passive film. The passive film breakdown occurs only in isolated locations such as weak spots in the film due to the presence of inclusions or other defects in the underlying metal. These isolated locations of breakdown develop as pits. Pitting attack is favored by certain environmental conditions:

- High chloride concentration
- High temperature
- Oxidizing conditions
- Low pH
- Stagnant or low-velocity conditions

A newly initiated corrosion pit tends to repassivate unless the conditions for its initiation are maintained (corrosion potential above the breakdown potential). Figure 15 is a schematic diagram of the pitting process.

If the pits do not repassivate they will become anodic with respect to the surrounding metal. Once a pit has become established, the driving

force for its growth is the development of an oxygen concentration cell. The surrounding metal surface remains passive because it has ready access to dissolved oxygen. Reduction of dissolved oxygen on the surrounding metal is the cathodic half of the net corrosion reaction. Anodic dissolution of metal in a pit can occur at a very high rate since the surface area of the pit is much smaller than that of the surrounding metal surface. Subsequent hydrolysis of dissolved metal complexes inside the pit results in the generation of free hydrogen cations. Anions diffuse into the pit from the outside by the process of electromigration to maintain electron neutrality of the solution in the pit. Of the available anions in the white-water solution, chlorides are the most mobile and can enter the pit more readily than larger anions such as sulfate. Generation of hydrogen cations due to metal ion hydrolysis and the electromigration of chloride anions into the pit can produce an environment inside the pit that resembles hydrochloric acid more than it does white water. Pit growth may then accelerate as acid corrosion.

Once pitting corrosion has become established, it is difficult to stop. Lowering the corrosion potential below the breakdown potential by eliminating the presence of residual bleach plant oxidants may not stop pitting corrosion until a substantially lower potential value is reached (the repassivation potential).

Crevice corrosion is a form of localized corrosion that occurs beneath deposits or in other areas shielded from direct contact with dissolved oxygen in the white water. Crevice corrosion resembles pitting corrosion (both are sustained by oxygen concentration cells), but crevice corrosion initiates more readily than pitting corrosion because the conditions for an oxygen concentration cell already exist with a crevice. The metal inside a crevice has difficulty maintaining passivation due to restricted access to dissolved oxygen. The inside of the crevice becomes anodic (metal dissolution) while the surrounding metal becomes cathodic (oxygen reduction).

White-water system closure can result in chloride concentrations and temperatures exceeding the values required for localized corrosion breakdown. Resistance to pitting corrosion of new or replacement equipment can be accomplished by selecting stainless steel having higher molybdenum content. Type 304L stainless steel contains no appreciable molybdenum and is highly susceptible to localized corrosion in closed white-water systems. Type 316L stainless steel has a specified molybdenum range of 2 to 3%, although modern type 316L typically contains molybdenum at the very bottom end of this range. Type 317L stainless steel has a specified molybdenum content of 3 to 4% and is more resistant to localized corrosion than type 316L stainless steel.

Thiosulfate Pitting. Thiosulfate is an aggressive pitting agent especially for type 304L stainless steel. Thiosulfate pitting can only occur below the potential for thiosulfate reduction,

unlike chloride pitting that occurs only above the passive film breakdown potential (Ref 93, 96). A reduction of thiosulfate in the presence of hydrogen ions produces an adsorbed sulfur monolayer on the metal surface. The adsorbed sulfur activates the anodic dissolution of the metal and hinders repassivation. Excess hydrogen ions must be present for acidification of the pit; further, there must also be a larger amount of inert ions (sulfate and chloride) that can be transported into the pit to meet charge transfer requirements and take part in metal-complexing hydrolysis reactions. The worst case of thiosulfate pitting occurs within the molar concentration ratio:

$$((\text{Na}_2\text{SO}_4 + \text{NaCl})/\text{Na}_2\text{S}_2\text{O}_3) = 10 \text{ to } 20$$

Above this range (ratio > 20) there is insufficient thiosulfate to reach the pit nucleus. Below this range (ratio < 10) there is too much thiosulfate reduction to bisulfite, which prevents acidification of the pit.

Once formed, thiosulfate pits are very stable and not subject to spontaneous repassivation. Scratches encourage the initiation of pits. Sensitization makes the heat-affected zones of welds particularly susceptible to thiosulfate pitting. A few large pits tend to form in thiosulfate pitting rather than many small pits that form in chloride pitting. Type 316L stainless steel is the minimum grade that should be used for white-water service where high thiosulfate levels may exist. In practice, it appears that corrosion problems can be mitigated if thiosulfate levels are controlled below 5 and 10 ppm for equipment made using types 304L and 316L stainless steel, respectively.

Microbiological Corrosion. Paper machine white waters contain nutrients that can sustain bacterial growth particularly if the pH is near neutral. White-water temperatures within the range of 40 to 50 °C (105 to 120 °F) also favor microbiological growth. Higher temperatures may prevent the growth of some forms of bacteria, although the increased temperatures can increase the metabolism of those bacteria that can adapt to heat. The result is the formation of slimes (Ref 78, 99).

Stock and white-water flow systems are designed to minimize slime accumulations. Surfaces are polished and weld projections removed to prevent pulp hang-ups. MIC can occur wherever slime deposits develop (Ref 100). Once a slime deposit has grown to a sufficient thickness to exclude oxygen, a colony of sulfate-reducing bacteria (*Desulfovibrio desulfuricans*) can become established. Enzymes produced by these anaerobic bacteria catalyze the reduction of sulfates resulting in the formation of free sulfide ions. Chemically reducing conditions quickly develop that result in the depassivation of the stainless steel surface beneath the deposit. Active corrosion, in the form of large shallow pitting, then takes place. The pits are characteristically covered with a black crust. Pitting perforations through stainless steel equipment due to MIC are usually small

Fig. 15 Pitting corrosion process in paper machine white water

since the entry of oxygen at a leak will stop the activity of sulfate-reducing bacteria.

Suction Roll Corrosion

Max D. Moskal, Mechanical and Materials Engineering

Suction rolls are used to remove water from paper at the wet end of the paper machine (Fig. 14). The paper web is passed through a roll nip, one roll of which is the suction roll. The suction roll is drilled with a pattern engineered to provide the required water removal and suction roll shell strength. A vacuum is applied to the inside of the roll to draw the water through the web and into the roll. Rubber or plastic coatings are used in either the suction roll or the mating roll to give the desired nip pressure for optimized water removal. Different paper machine designers will use suction rolls in different loca-

tions with water-removal schemes designed for their specific machine configuration.

Suction rolls are part of the paper machine and are usually drilled to about 20% open area. They are used to remove water from paper at the wet end of the paper machine. Prior to 1950, suction rolls were cast from copper alloy C83600 (85Cu-5Sn-5Pb-5Zn). As paper machine width, speed, and nip pressure increased, stronger alloys were introduced: nickel aluminum bronze, forged stainless steel type 410 (S41000), and centrifugally cast stainless steels CA-15 (J91150), type CF-3M (J92800), and CF-8M (J92900).

Suction roll speeds and nip pressure continued to increase, and failures of these roll materials led to the introduction of special grades of cast and wrought duplex stainless steels. The composition of suction roll alloys is given in Tables 5 to 7. Tables 5 and 6 show currently available suction roll alloys. Table 7 shows alloys, many of which are still in use, that have been discontinued by producers in favor of the alloys shown in Table 6. In the selection and performance of suction roll materials, corrosion resistance and fatigue strength in paper machine

white water, nip pressure, roll width, and residual stress level all play important roles.

Corrosion

Corrosivity of the white-water environment is largely predetermined. However, the papermaker can still exert some control. Following the practices outlined in Ref 101 can reduce sulfate ion contamination and residual hydrosulfite, which can be especially damaging.

Freshwater showers of the suction rolls provide more effective cleaning and also reduce corrosive effects. Good maintenance of the roll is an important factor in minimizing corrosion. Drilled holes must be kept clean of deposits by the use of needle showers and periodic off-machine cleaning. A careful program of biological control should be maintained. The papermaker should also avoid the use of cleaning chemicals (such as muriatic acid) that are known to damage shell alloys and roll covers.

Operating Stresses

Both the applied stress and internal residual stresses (inherent in the shell material) contribute to the stress in operation of the suction roll. The responsibility for the level of applied stress rests chiefly with the roll designer. Each shell material will have an upper limit of applied stress that will give long life in a particular environment. The magnitude of this stress is a function of roll configuration and applied loads.

Drilled hole patterns are designed to reduce the effects of applied stress. The most important factor influencing the applied stress is shell thickness. Applied stress decreases as the shell

thickness increases. A stress calculation procedure has been developed by the Technical Association for the Pulp and Paper Industry (TAPPI) to use as a guide for determining stresses in suction rolls (Ref 102), although there is little agreement among roll manufacturers as to how to make this calculation. The TAPPI procedure was recently modified so that stress calculations can be made on a personal computer. While the TAPPI procedure still needs to be refined, it provides mill personnel with a uniform method for determining minimum thickness requirements and drill patterns and for evaluating roll failures regardless of the roll manufacturer.

Gun-drilled or reamed holes for improved surface finish also reduces corrosion and improves the cleanliness of drilled holes in service. Gun-drilling or reaming is usually not performed on bronze shells.

Residual stress that originates in the alloy and from the heat treatment is also an important factor contributing to roll life. Shells made from materials with known high residual stresses should be designed more conservatively or, preferably, not used at all.

Manufacturing Quality

There is little published information relating to suction roll manufacturing quality. Rolls should be inspected using liquid penetrant prior to drilling to detect flaws such as porosity, slag, and cracks (Ref 103). Skillful control of melting and casting procedures can minimize these defects. Weld repairs should be used with discretion and only before shell heat treatment. Type 1N bronze should not be weld repaired because of the hot shortness that develops in the alloy. Careful attention should be given to drilling and machining quality and dimensional control. Industry-wide standards giving acceptance criteria for casting flaws and drilling quality have not been developed.

Material Selection

When a new or replacement suction roll is contemplated, the question of material selection is of primary importance. Selection of a new alloy should involve an evaluation of the existing roll condition and the factors contributing to its deterioration. Changes in the corrosion environment that have occurred on the paper machine should also be evaluated. The temptation is to select an identical alloy if the previous material served for 15 or 20 years. However, it is likely that changes in the machine environment have occurred during that period and that the life of a new roll of the same alloy could be substantially reduced. Furthermore, the roll material in use may have been superseded by an improved alloy and no longer be in production. Table 7 lists suction roll alloys that have been discontinued by manufacturers.

Most suction roll vacuum boxes on older paper machines were manufactured using epoxy painted cast iron. More recently, manufacturers have used weld fabricated type 316L (S31603) stainless steel suction boxes to better resist corrosion damage.

In-Service Inspection

Periodic inspection of the suction roll is a critical step that helps extend roll life and minimize unexpected shutdowns. Rolls should be removed from the machine, disassembled, and thoroughly cleaned, then inspected. The inspection interval is determined by local experience and is normally about once a year. Inspection should include an evaluation of drilled hole cleanliness, fatigue cracking of the shell, and rubber cover deterioration or detachment. A careful visual examination is made for corrosion and cracks. Water-washable liquid penetrant has been successfully used to detect cracks on the inside and outside surfaces.

When cracking is observed during an annual inspection, immediate consideration must be given to replacement because of the long lead time required for shell manufacture. Consideration should also be given to inspecting the roll more often than once per year to observe the rate of crack growth. A careful record must be made whenever cracks are observed. TAPPI TIP 0402-19 (Ref 104) provides guidelines for suction roll inspection. TAPPI TIP 0402-01 (Ref 105) provides a standard form for documenting inspection results and roll failures.

Corrosion Control in Chemical Recovery

David Bennett, Corrosion Probe Inc.
Craig Reid, Acuren

This section addresses corrosion and chemical recovery associated with kraft pulping liquors. As mentioned previously in this article, the kraft process is the most commonly used pulping process used in North America.

Black Liquor

Black Liquor Evaporation. The flow diagram of the chemical recovery system of a typical kraft mill is shown in Fig. 16. The cyclic recovery processes recover the inorganic chemicals (white liquor) used to cook or digest the wood chips. First the black liquor is evaporated so that it is dry enough to be burned. Second, the reduced, molten smelt produced in the recovery boiler is dissolved in water to make green liquor. This is then causticized to produce the white

liquor. Organic chemicals dissolved out of the wood are the fuel portion of the black liquor fired in the recovery furnace. This combustion also raises steam for energy generation and for process use.

After separation from the pulp in brown stock washers, weak black liquor at a concentration of about 15% solids is pumped to a multiple-effect evaporator (MEE) in which solids are concentrated to at least 50%. Further evaporation of the black liquor in a concentrator or direct contact evaporator increases solids content still higher so it has enough heat value to be the primary fuel in the recovery furnace.

Black liquor inorganic constituents are mostly sodium carbonate and sodium sulfide with other constituents as listed for a typical composition for a southern pine sulfate kraft black liquor leaving the digester. The pH is 11.6 and the concentration is 23% solid:

Component	Composition, gm/L
Sodium sulfide	4.9
Sodium hydroxide	6.8
Sodium sulfate	2.0
Sodium carbonate	55.9
Sodium trisulfate	14.3
Sodium chloride	0.17

Pulp mills with a chemical recovery process utilize a series of MEEs similar to that shown in Fig. 17 to make the liquor concentrated enough for combustion in the recovery boiler. Multiple-effect evaporator systems vary as to the number of evaporators, concentrator systems, capacity, and so forth. Most evaporators are steam heated, using either shell-and-tube or falling-film heat-exchanger designs. Figure 18 shows a schematic of a falling-film unit.

Some kraft mills concentrate the black liquor to around 80% solids, but most mills concentrate the liquor to somewhere in the 65 to 75% solids range. The high temperatures associated with evaporating the black liquor above about 40% solids make stainless steels essential for the liquor-wetted surfaces. Stainless steel heat-exchanger surfaces are more or less universal in all evaporation stages.

Carbon steel may still provide satisfactory corrosion resistance in the bodies of the first two or three evaporation effects (these usually are the highest-numbered effects), especially where liquor temperatures are below 95 °C (200 °F). Although the exact mechanism for corrosion of carbon steel in black liquor is not fully understood, the tenacity of the self-protective passive film is a crucial factor.

Stainless steels, with their much more tenacious passivity, have a favorable history of resisting corrosion in all black liquor environments. As a result, stainless steels are used both to repair existing equipment where carbon steel has corroded and in new equipment where corrosion of carbon steel might be expected.

The MEEs from the third or fourth to the first effects and the concentrator are always made completely of stainless steel, most often type 304L (S30403). Many mills have used thermal

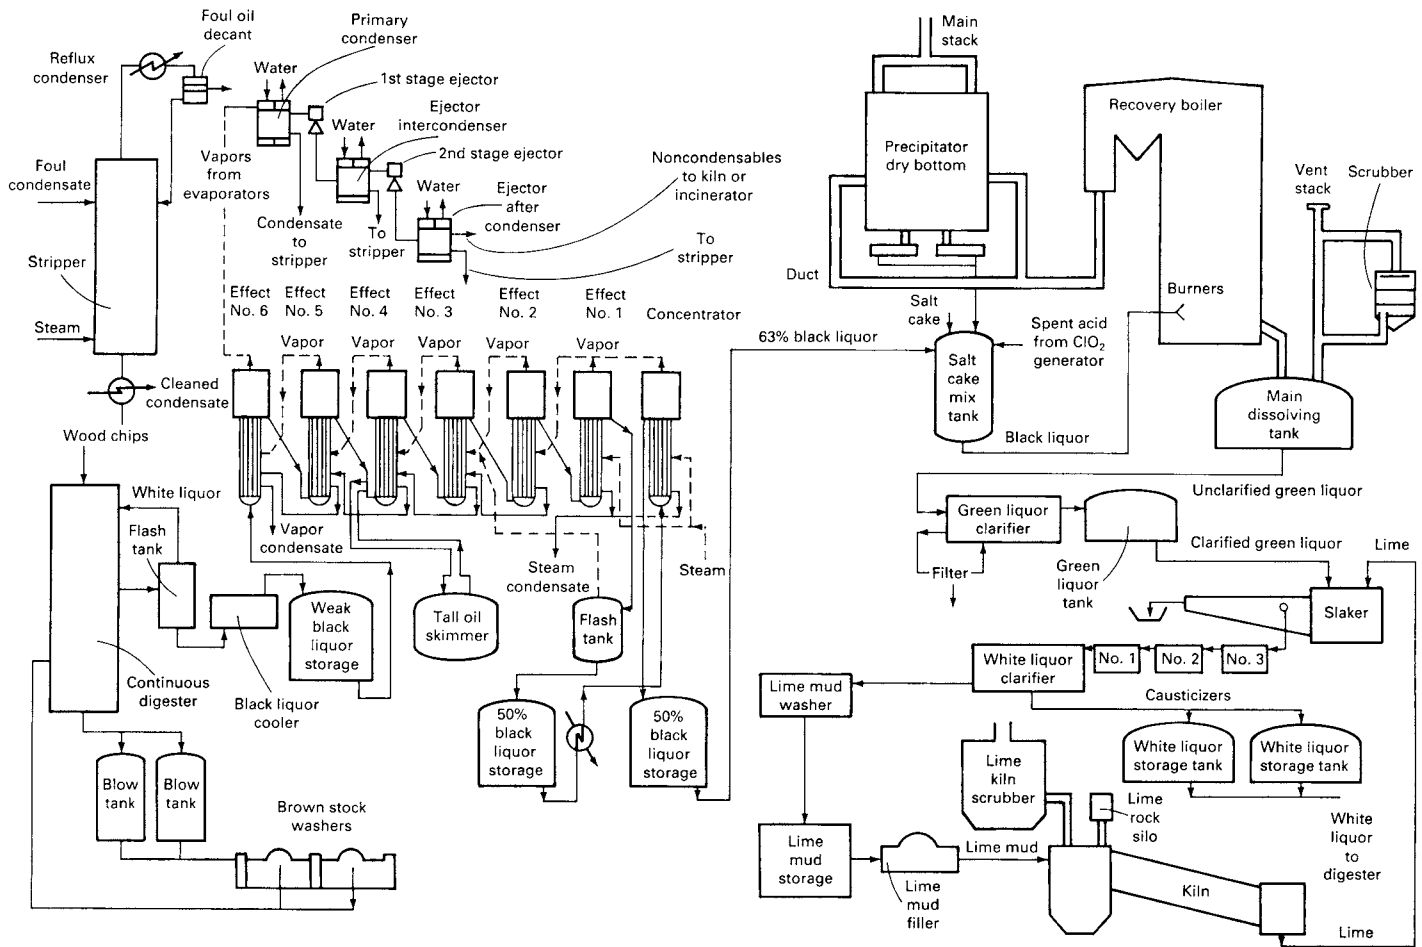

Fig. 16 Flow diagram of kraft pulping and chemical recovery

Fig. 17 Multiple-effect evaporator/concentrator design

spray coatings or sheet linings of duplex or austenitic stainless steel to protect carbon steel components against liquor corrosion. It is sometimes necessary to protect the carbon steel

tube sheets and vapor zone target areas in MEEs with corrosion barriers.

In liquors concentrated to higher than about 70% dry solids, type 304 and type 316 con-

Fig. 18 Cross-sectional view of a falling-film black liquor evaporator and concentrator design

centrator tubing is subject to both significant general corrosion and to caustic stress-corrosion cracking. Rapid, localized corrosion can develop in areas of higher flow velocity or increased turbulence. Caustic cracking is believed to occur

because at these high dry solids environments, the temperatures, and caustic concentrations are entering ranges where both types 304L and 316L are subject to stress-corrosion cracking (SCC). The solution is to either use more highly alloyed austenitic stainless steels or to use duplex stainless steels that are more resistant to both caustic cracking and to corrosion in high turbulence areas.

Waste streams, such as sulfuric acid effluent from the tall oil plant and spent acid from chlorine dioxide operations—both are sources of sulfates for maintaining the sulfur balance—may be added to the evaporator black liquor stream before the first effect or concentrator. This sometimes makes liquors too corrosive for type 304L stainless steel, especially if the residual alkalinity in the liquor is eliminated by these additions. Higher alloyed austenitic steels are generally adequate for handling black liquors.

Stainless steels perform well as pumps, piping, tube sheets, liquor boxes, and surfaces subject to evaporator-related black liquor flow turbulence or splashing. Type 304L stainless steel is also widely used throughout the steam and condensate piping systems. This includes all vapor bodies, separators, condenser tubes, pumps, and piping.

This discussion has concerned sulfate (kraft) and soda (i.e., alkaline) spent liquor evaporators. Evaporators for acid (i.e., sulfite) spent liquors require type 316L (S31603) or higher molybdenum content stainless alloys for all liquor and vapor contacted surfaces. Evaporators for neutral pulping (sulfite semichemical), in which the liquors have lower but still alkaline pH and a higher concentration of sulfite ions, normally use type 316 (S31600) stainless steels for heat-exchanger tubing and other liquor contacted surfaces.

Black liquor oxidation is carried out in many mills as an odor-control measure. By oxidizing the liquor, hydrogen sulfide (H_2S) and mercaptan levels in evaporator condensate and in the noncondensable phases are reduced. Oxidation of sulfides in the liquor to thiosulfate also reduces the hydrogen sulfide content of the boiler flue gas.

As with all liquor handling equipment at elevated temperatures, tanks, piping and other components for black liquor oxidation are most often made of type 304L stainless steel.

Black Liquor Tanks. Black liquor may be stored at 30% solids, which is a typical liquor concentration in soap separation tanks, as well as in the more concentrated “heavy black liquor” form, which may be stored before or after the liquor concentrator.

Black liquors must be kept hot for easier pumping. This makes corrosion of carbon steel in black liquor service unpredictable. Stainless steel construction, most commonly with type 304L, can minimize corrosion in black liquor tanks and is essential to avoid flow-induced corrosion around agitators and in pumps and piping. There is also one report of SCC in the tidal zone of type 304L tanks storing 72% solids

black liquor. The tanks are located in a mill processing seawater floated logs. In this same mill type 304L tanks storing 50% solids black liquor have shown no signs of corrosion or SCC after more than 15 years.

Stainless steel sheet linings can protect corroding surfaces in carbon steel tanks, provided the lining is properly designed to remain intact. Stainless steel linings also are used in carbon steel flash tanks on continuous digester systems.

A significant amount of welding is involved in properly installing a stainless steel lining because the dimensions of each lining panel must be small enough to minimize thermal expansion effects and avoid subsequent weld cracking. Another drawback of internal linings is the challenge of inspecting for corrosion behind the lining.

For new black liquor tanks, it is generally more economical to specify solid stainless steel construction instead of using clad material or lining a carbon steel tank. Clad material at the thicknesses involved (<15 mm, or 0.6 in.) is usually more expensive than solid stainless steel plate.

Storage tanks in a mill with high chloride levels in the heavy black liquor have experienced internal SCC and pitting in the wet-dry region of the walls. Testing showed that 6% Mo stainless steel adequately resisted the unusually aggressive environment in these tanks.

Appropriate inorganic corrosion-resistant linings can provide good chemical resistance to black liquor at all concentrations and temperatures.

Chemical Recovery Tanks

Smelt Dissolving Tank. The molten smelt is quenched and dissolved in a large tank with internal agitators—the smelt dissolving tank—to produce green liquor. This tank rumbles continuously, and the heat produced by heavy smelt inflows can cause significant hydraulic pulses. Most dissolving tanks have extra-thick walls and are made of carbon steel.

Internal corrosion protection is usually required because the agitated contents have a high content of abrasive, suspended solids. The continuous flows around agitators and the hydraulic pulsing help the heavy suspended solids content cause erratic, localized erosion-corrosion of carbon steel. Erosion-corrosion of carbon steel can also occur behind linings that are breached and are not sufficiently tightly attached.

There are three general ways to prevent corrosion in dissolving tanks:

- Stainless steel construction with weldable 12% Cr steel, type 304, or alloy 2205 (S32205) stainless steel
- Sheet lining with type 430 (S43000), type 304, or alloy 2205 stainless steel and proper lining design
- Lining with a reinforced, inorganic cementitious material

All stainless steels have good corrosion resistance in green liquor immersion. Duplex and ferritic stainless steels resist SCC above the liquid level better than types 304L or 316L. Solid stainless steel dissolving tanks are increasingly common. Pumps, agitators, and nozzles that regularly see flow conditions are made of stainless steel. Duplex stainless steels are more resistant than austenitic grades to abrasive erosion-corrosion, such as experienced by agitator blades, due in part to the higher hardness of duplex stainless steel.

Green Liquor Tanks. Carbon steel green liquor tankage corrodes most rapidly where air dissolved in the green liquor produces thiosulfate ions. This usually occurs—and limits the worst corrosion to—half a meter or so immediately below the liquor level. Fluctuating levels reduce thinning rates by spreading the corrosion over a wider area.

Stainless steels such as austenitic type 304L and duplex grades such as alloy 2304 (S32304) or alloy 2205 have excellent corrosion resistance in all green liquor service conditions, including pumps and piping. Newer duplex stainless steels with lower molybdenum and nickel contents are also likely to perform well in green liquor service. A 12% Cr stainless steel also is suitable for green liquor tank construction. Special care should be taken when using hydrochloric acid to remove carbonate scale buildup since corrosion of these stainless steels can occur even if the acid is inhibited.

Many carbon steel clarifiers and tanks in green liquor service have internal stainless steel linings or solid plate inserts to prevent corrosion. Solid type 304L stainless steel also is widely used for rakes, internal piping, and nozzles.

Slakers and Causticizers. Slakers are tanks in which calcined lime is converted to calcium hydroxide, or a lime solution. The lime solution is added to the green liquor in the causticizer tanks to convert the sodium carbonate to sodium hydroxide, making white liquor from green liquor.

Slaker and causticizer environments are strongly alkaline and have high levels of suspended particles. The abrasion-erosion effects of the suspended materials can cause rapid corrosion of carbon steel where protective scales or deposits do not form. The abrasion from these suspended materials normally has an aggressive “polishing” effect on stainless steels. Harder stainless steels such as the duplex grades or work-hardened austenitic grades are significantly more resistant to this abrasive “polishing” mechanism.

Slaking and causticizing tanks are typically constructed of stainless steel or of carbon steel with an inorganic lining, commonly a gunned, sulfate-resistant, portland cement-based material. Pumps and piping are the standard grades of stainless steel or duplex grades to better resist the abrasive conditions.

White Liquor Tanks. White liquor is clarified or filtered and then stored in tanks. Onset and rates of carbon steel corrosion are very

unpredictable in white liquors. Aeration of white liquor produces intermediate, oxidized sulfur species such as thiosulfate or polysulfide. These chemical species affect the passivity of carbon steel and can increase corrosion, although polysulfide levels higher than about 2% help stabilize the passive surface layer, thereby reducing carbon steel corrosion.

Stainless steel is fully corrosion resistant to white liquor due to its significantly more tenacious passive film. Types 304 and 316 are subject to intergranular cracking in white liquor at temperatures above 70 °C (160 °F) when sensitized by welding. Sensitization can be avoided by specifying the low-carbon grades, for example, type 304L, or a duplex stainless steel.

Molybdenum-containing stainless steels such as types 316L and 317L (S31703) have measurably poorer corrosion resistance than 304L in white liquor environments. Duplex stainless steels, with their higher chromium content, have better corrosion resistance than 304L. They also perform better under erosion-corrosion conditions, where the higher hardness of the duplex stainless steels contributes to their superiority. There are also recently commercialized grades of duplex stainless steel with lower alloying content to reduce material costs but good corrosion resistance in white liquor service.

For liquor heaters, tubes of alloy 2205 stainless steel, 26% Cr ferritic stainless steel (e.g., S44660), and nickel (or nickel alloys) all outperform type 304, which can experience internal corrosion at temperatures above 150 °C (300 °F) and also experience SCC, especially from the steam side.

As mentioned previously for green liquor piping, acid cleaning austenitic stainless steel tubes in white liquor heaters with hydrochloric acid can damage the tubes. Pitting and SCC can occur with even short exposure to hot hydrochloric acid, even if the acid is inhibited.

Clarifier rakes, piping, pumps, valves, nozzles, and so forth for white liquor service are type 304L or alloy 2205 wrought stainless steel, or CF-3 (J92500) or CD-4MCuN (J93372) castings. As with wrought materials, duplex stainless steel castings have higher resistance to erosion-corrosion than austenitic stainless steel castings.

Additional Considerations for Tanks in Black Liquor, Green Liquor, and White Liquor Service

As stainless steel replaces carbon steel for these chemical recovery tanks, two important

precautions are sometimes overlooked. First, when hydrotesting newly installed stainless steel tanks, it is necessary to drain the water used for hydrotesting or place the tank in service promptly to avoid microbiologically influenced corrosion (MIC). Microbiologically influenced corrosion has been reported in type 304L (and 316L) tanks in a number of cases where water used for hydrotesting was left in the tank for a month or more. It is important to drain the water completely since MIC can also occur in water left in the bottom of incompletely drained tanks. Microbiologically influenced corrosion has not been reported when tanks have been placed in service within a few days of hydrotesting.

Second, the exterior of type 304L tanks is subject to SCC under the insulation, especially when the insulation is regularly wetted, for example, by rain or leakage from nearby lines. Underinsulation SCC has been such a frequent occurrence that NACE International developed a Standard Recommended Practice: "The Control of Corrosion under Thermal Insulation and Fireproofing Materials" (RP 0198). This document outlines good practices to prevent underinsulation SCC. Duplex and more highly alloyed stainless steels are far less susceptible to MIC and chloride SCC. However, both draining promptly after hydrotesting and keeping the insulation dry are good anticorrosion practices to follow, regardless of the material of construction.

Lime Kiln and Lime Kiln Chain

Lime Kiln. Lime mud from the white liquor clarifier is washed and fed to the lime kiln, where moisture is driven off and calcium oxide is formed. This is added to the green liquor to make white liquor. The lime mud is conveyed into the chain section of the kiln by a short section of spiral flights welded to the kiln shell. Progressing into the kiln from the feed end, four zones of the chain section can be defined (Table 8). The carbon steel shell in the hot end of the kiln is protected with heat-resisting brick, but the kiln internals can be subject to corrosion and mechanically enhanced corrosion and cracking.

In the first zone, the kiln shell and the flights in the conveying section are subject to moderate abrasive corrosion and alloy 2205 duplex stainless steel has been used for the flights and to line the kiln shell to better resist the abrasion in zones 1 and 2.

Lime Kiln Chain. Heavy chains are used to collect heat from the hot exit gases and transfer

the heat to the lime mud to evaporate the moisture from the mud. The chain section in the kiln can be 15 m (50 ft) or more long, so the chain nearest the burner is subject to both convective and radiative heat transfer.

Carbon steel and low-alloy steels can be used for the first two zones of chain if the metal temperature does not exceed 500 °C (930 °F). Cast or wrought stainless steel chain is required in the hotter zones where chain life is determined by scaling rather than by wear. Both austenitic and ferritic stainless steels are used. Selection is based on experience in a particular kiln and cost.

Austenitic stainless steels are considerably stronger than the ferritic stainless steels above about 540 °C (1000 °F). Type 304 stainless steel or its cast equivalent CF-8 (J92600) can be used in zones 2, 3, or 4. Special heat-resisting grades are also available for zone 4.

Type 304 stainless steel chain:

- Has reasonable oxidation resistance up to 815 °C (1500 °F)
- Can be exposed for 10,000 h at 650 °C (1200 °F) and still retain adequate room-temperature ductility
- Has a reasonable creep rate at 650 °C (1200 °F)

While type 304 is the basic alloy used for lime kiln chain, other alloys with better resistance to high temperatures are also used. Table 9 shows some aluminum- and silicon-alloyed ferritic stainless steels used for lime kiln chain.

The calcined lime discharged from the kiln passes through lump-crushers and grizzlies and is conveyed away from the lime kiln by a drag chain. Typically, HH (J93503) and HN (J94213) cast stainless steels are used for grizzlies and chain links, while type 310 austenitic stainless steel is used for chain pins. Table 10 gives the composition of these stainless steels.

Sulfuric acid is the principal corrodent in tall oil plants. Carbon steel has good resistance to strong 98% sulfuric acid and is the principal material used for strong acid storage tanks. Flow disturbs the protective sulfate film that protects carbon steel; therefore, type 316L (S31603) is normally used for piping. Type 316L is also useful in weak sulfuric acid at low temperatures. Copper additions to stainless steel improve corrosion resistance to sulfuric acid. Alloy 20, which was developed for sulfuric acid service and has 3.5% Cu, is the principal upgrade in North America. Alloy 904L, which has 1.5% Cu, is the principal upgrade in Europe when concentrations and temperatures are too high for satisfactory performance for type 316L. In the

The diagram illustrates a chemical process flow involving a reactor and several downstream units. The process starts with an in-line mixer where Soap feed (CS), H₂O (CS), Fresh acid (CS), and an alternate Waste acid (PLSP) are combined. This mixture is then sparged with steam (SS) into a Reactor (FRP, SS, or lead-lined). The Reactor also receives Dispersant (SS) and White liquor (CS). The output from the Reactor passes through in-line strainers (SS) and a vibrator screen (SS) to separate fiber solids. The liquid stream then goes to a Centrifuge feed tank (300 gal FRP). From there, it splits into two paths: one to a Centrifuge (SS) which sends spent acid/brine (SS or FRP) to a Spent acid/brine vat (FRP), and another to a Spent acid/brine neutralizing tank (200,000 gal FRP or SS). The Spent acid/brine vat also receives White liquor (CS) and sends material to recovery or weak liquor (CS). The Spent acid/brine neutralizing tank also receives White liquor (CS) and sends material to recovery or weak liquor (CS). The Spent acid/brine vat also sends material to storage (SS) via a CTO.

Chemical species, other than chlorides, and including organic species, often present in sulfuric acid, can have a significant effect on corrosivity. The positive or negative impact of other species present on corrosivity, and the nature of sulfuric acid itself, tend to make alloy selection site specific. The article "Corrosion by Sulfuric Acid" in this Volume should be consulted for additional information.

Corrosion in Recovery Boilers

Douglas Singbeil, Paprican

Recovery boilers in the pulp and paper industry are large, fuel-to-energy boilers designed to combust organic waste from the pulping process (Ref 111). They are similar in many respects to other types of boilers, including those that burn coal, municipal waste, and wood-waste or bark, and are prone to many of the same corrosion and materials issues. What differentiates recovery boilers is their function as a chemical reactor (Ref 112). Their role of recovering the spent inorganic cooking chemicals and converting them into forms suitable for reuse in the pulping process is paramount over steam and energy production.

Most recovery boilers in the pulp and paper industry burn kraft process liquor (black liquor) as a fuel, although sulfite and neutral carbonate liquors are also burned. As a consequence, the Tomlinson furnace, or kraft recovery boiler, is the focus of the balance of this section. The first Tomlinson furnace entered service in the late 1930s, but the design has evolved significantly

Fig. 22 Typical kraft recovery boiler used in the wood pulp industry. This is a modern, single-drum design, with the steam drum located outside the gas passage. Most boilers built prior to 1990 incorporated a generating bank, with an upper steam drum and lower mud drum, in place of the boiler bank and external steam drum. Courtesy of the Babcock & Wilcox Company

over the decades and modern kraft recovery boilers bear little resemblance to the original boiler. The basic components of the modern recovery boiler have been in place since the late 1960s, and in North America many boilers still date from this era, although most have been upgraded or substantially rebuilt.

A typical modern recovery boiler (Fig. 22) built in the period 1995 to 2005 processes upward of 3000 tonnes (3300 tons) dry solids fuel/day, operates at a steam pressure of between 8.3 and 12.4 MPa (1200 and 1800 psi), and produces as much as 150 kg/s (330 lb/s) of steam. Older recovery boilers are generally smaller, and many operate at lower steam pressures, some as low as 4.1 MPa (600 psi). Water-

cooled tubes make up the floors and walls of the furnace cavity, while the heat from combustion gases is extracted by superheaters, a boiler bank, and economizers before the gases exit the boiler. In modern boilers, wall and floor panels are made with sealed membranes between tubes, although sealed and unsealed tangent tube construction has been used in the past. Black liquor is delivered to the boiler as a hot, aqueous slurry at between 63 and 85% solids content. The black liquor is fed into the boiler from all four walls through liquor guns, which are tubes fitted with a nozzle, most commonly just a splashplate designed to break up the spray of liquor into fine droplets as it enters the furnace (Ref 113). Depending on the boiler design and size,

anywhere from 4 to 12 liquor guns might be employed. Combustion air is typically added at three levels in the furnace (older designs may use only two levels, and some new designs incorporate as many as 4 to 6 levels). A less than stoichiometric amount of air is added through the lower, primary air ports, with the balance being added through secondary and tertiary air levels.

Approximately 20 to 25% of the dry solids in black liquor are inorganic chemicals (Table 11) (Ref 114). It is critical to the process that the sulfur and soda content from the inorganic compounds be recovered and, at the same time, that the sulfur-containing salts are reduced back to the sulfide form necessary to catalyze the dissolution of lignin from wood chips. These latter reactions are endothermic and only occur at high temperatures in the presence of carbon char, or other reducing compounds—hence the need for the recovery boiler.

As the liquor burns, it goes through a sequence of discrete steps that include drying (evaporation of water), pyrolysis, and devolatilization (release of organic and inorganic volatile gases), char burning (production of CO and CO₂), and finally reactions between remaining molten salts (Ref 115). The hot combustion gases that are produced carry with them a fraction of the sodium (in the form of carbonate) and sulfur (as sulfate). The balance of the inorganic salts flow down the walls or fall to the bottom of the boiler to form a molten pool of smelt that is decanted off in a continuous stream through spouts into a dissolving tank. Depending on the boiler manufacturer, the floor might be flat (fully decanting) or sloped at a small angle outward toward the spout openings or inward toward a common center header. The top of this molten smelt pool is usually covered by a porous layer of char, in which the bulk of the reduction reactions occur as the molten salts pass through it.

Recovery Boiler Corrosion Problems

Corrosion of the component parts in a kraft recovery boiler has been a major challenge for the industry. It limits the overall energy efficiency of the boiler, largely due to restrictions placed on maximum steam temperatures to

prevent molten salt corrosion of the superheater tubes. In addition, the hot, molten pool of inorganic salts (smelt) at the bottom of the boiler can react with water to create a very energetic, and often catastrophic, explosion. Consequently, unlike most other types of boilers, kraft recovery boilers cannot tolerate even the smallest leak of water into the furnace cavity. Complete destruction of the boiler, and corresponding risks to operating personnel, could result.

All kraft recovery boilers are subjected to a strict regimen of inspection and repair designed to identify and rectify problems before they compromise the safe operation of the boiler (Ref 116). Nonetheless, tube leaks do occur. Historically, about 40% of smelt/water explosions in kraft recovery boilers have been a consequence of a pressure part failure, although the modern record is much improved (Ref 117).

Fire-side corrosion problems to which kraft recovery boilers are susceptible include:

- General corrosion
- Fatigue
- Corrosion fatigue
- Stress-corrosion cracking

Water-side corrosion problems include:

- Overheating
- Stress-assisted corrosion
- Oxygen pitting
- Flow-assisted corrosion

As might be expected for a reactor design that has been in a steady state of evolution for nearly 80 years, and with models in operation

from numerous manufacturers, many corrosion problems have been specific to certain designs or methods of manufacture (Ref 118). Many of these historical problems no longer affect modern recovery boilers and are not mentioned here. The water-side corrosion problems to which recovery boilers are subjected are similar to those found in other boilers, and reference will be made to these only in passing. Readers are referred to other articles in this Volume for more information on these types of problems. See, for example, the article "Corrosion of Steam-land Water-side of Boilers" in this Volume.

Corrosion in the Lower Furnace

The following paragraphs describe the general fire-side environment responsible for corrosion in each section of a recovery boiler, providing comments on common problems prevalent in modern recovery boilers, as well as ways to resolve them. Most of the discussion is focused on issues that affect pressure parts, rather than attachments and other noncritical parts of the boiler. For reference throughout this section, a list of alloys that are commonly used in recovery boilers is shown in Table 12.

The environment in the lower furnace of a recovery boiler is a maelstrom of liquor, char, particulate, combustion gases, and molten salts. The liquor entering the boiler is not homogeneous; composition and calorific value change rapidly, which affects both the combustion and distribution of liquor into the furnace. The lower waterwalls of the furnace are always

covered by layers of both molten and solid salts, as well as residual liquor and char. The depth of the molten smelt/char bed on the floor of the boiler can vary from as low as 100 to 200 mm (4 to 8 in.) around the edges, up to more than 2 m (6 ft) high in the center of the boiler. The molten smelt on the floor of the furnace is typically at a temperature of 750 to 850 °C (1400 to 1560 °F), while the combustion gases above the bed are generally hotter than 1000 °C (1800 °F). The combustion gases in this portion of the boiler are reducing, due to the substoichiometric supply of primary air, and have been analyzed to contain as much as 5 vol% hydrogen sulfide (H₂S) as well as significant amounts of carbon monoxide (CO) and other reducing gases (Table 13) (Ref 119).

Corrosion of Carbon Steel Tubes. Surprisingly, the water-cooled tubes that make up the walls and floor of the boiler were made from ASTM A 210 grade A1 carbon steel (CS) or equivalent until the early 1970s, and this material is still in use today in many boiler floors and in the walls of older, low-pressure recovery boilers. The reason is simple—the first melting point of most deposits, including the smelt, in recovery boilers is never lower than about 500 °C (930 °F), while the tube surface temperature of a typical low-pressure (<6.2 MPa, or 900 psi) recovery boiler is not much greater than the water temperature in the tubes—about 300 °C (570 °F). A layer of insulating frozen smelt quickly forms on the tubes and acts as a barrier to corrosion. To aid in formation of the frozen smelt layer on the tube surface, and to keep it from sloughing off, carbon steel studs about 10 mm diameter by 25 mm long (0.5 in. diameter by 1 in. long) are generally resistance welded in a dense pattern to the surface of the tubes (Ref 120).

Studded carbon steel floor tubes have generally been free of corrosion problems (Ref 121). The most rapid corrosion of carbon steel wall tubes in the lower furnace occurs where the liquor lands on the walls in a zone from the top of the smelt bed to just below the secondary air-port openings (Ref 122). Estimates for average rates of corrosion on carbon steel tubes in the lower furnace vary from between 0.05 and 0.2 mm/yr (2 and 8 mils/yr) up to a maximum of 0.4 to 0.8 mm/yr (16 to 32 mils/yr). Much higher short-term wastage rates—as much as 5 mm/yr (200 mils/yr) are occasionally reported (Ref 123). The corrosion is manifested as general wastage of the tube surface, and analyses of

corrosion products invariably show they are composed of iron sulfide, with little or no iron oxide present. While wastage patterns of approximately 1 m² (11 ft²) or more are not unusual, small intense areas of localized corrosion are also found. These latter areas are often much smaller than the inspection grid spacing and present considerable challenges to locate before a tube rupture occurs (Ref 124). Overheating due to internal scale formation or nonuniform water circulation in a tube is sometimes, but not always, a factor that contributes to corrosion of carbon steel tubes.

The mechanisms responsible for corrosion of carbon steel tubes in the lower furnace are well understood. Due to the large temperature difference between the “cold” tube surfaces and the first melting point of the salts in the boiler, fluxing from molten salts is unlikely to contribute significantly to corrosion, except under unusual circumstances. Some corrosion may be the result of exposure to wet liquor, or hydrated sodium sulfide, but it is reactions between the steel and pyrolysis gases that circulate through the porous deposits adhering to the surface of the walls that are likely responsible for most of the observed corrosion. Long-term average corrosion rates can be readily accounted for by isothermal reactions between carbon steel, H₂O, O₂, and gaseous H₂S (along with other sulfur species) in the reducing atmosphere of the lower furnace (Ref 123). Additional factors have been identified as being particularly likely to contribute to accelerated corrosion (Fig. 23) (Ref 125):

- Organic sulfur compounds released from the liquor in large quantities during the early stages of pyrolysis. These gases (principally methyl mercaptan—CH₃SH) contribute to higher sulfur activities than H₂S and on an equal volume basis, CH₃SH is as much as 22 times more corrosive than H₂S at temperatures between 300 and 400 °C (570 and 750 °F).
- Increased temperature combined with temperature cycling. Carbon steel corrosion rates increase rapidly as temperatures approach 400 °C (750 °F), but cycling over a limited range of only 300 to 400 °C (570 to 750 °F)

will increase corrosion rates by a factor of 3 times or more over the highest isothermal rate.

- Cycling between oxidizing and reducing conditions, which accelerates corrosion rates of carbon steel by a factor of 2 to 3 times.

In practical terms, liquor droplets that hit the surface of the tubes are quickly covered by newly arriving material, including molten smelt running down the wall. As these droplets heat, pyrolysis gases, including H₂S and CH₃SH, are released to diffuse through a porous inner layer and react with the tube surface. Variations in the flux of droplets to the wall, and in the energy reaching the tube surface, account for the wide variability in corrosion rate that can be observed. Operating practices for the boilers and overall boiler design play a large role in determining the fraction of liquor droplets that reach the furnace walls before pyrolysis occurs. Controlling this problem, while meeting the process needs of the boiler as a chemical reactor, is a complex issue. Generally speaking, operating practices that promote liquor burning on the walls will also increase carbon steel corrosion rates.

Corrosion Control of Carbon Steel Tubes.

A number of strategies have been employed to mitigate corrosion of carbon steel tubes in the lower furnace. These include “studding” the tubes, applying protective coatings, or replacing carbon steel with more resistant alloys. Each of these options is discussed briefly below.

Studded tubes are still found in some low-pressure recovery boiler walls, and in the floors of many boilers, including higher-pressure units. On occasion, chromized studs (carbon steel with a thin chromium-rich surface layer applied by pack cementation) have been used instead of plain carbon steel. The cooling of the studs is not as efficient as on the tube surface, and over time the studs will corrode back to nubs, particularly in areas of the boiler subject to high local heat fluxes (Fig. 24). These high heat fluxes promote more rapid degradation of the studs and also encourage a wash of molten smelt over their surface that contributes to corrosion. Studding is a proven long-standing method of reducing the rate of corrosion on carbon steel tubes, but studded tubes are sometimes subject to the formation of numerous shallow, parallel notches in the tube between studs (often known as “elephant hide”), as well as deeper circumferential cracks at the base of the studs—both likely caused by intense cyclic thermal fluxes (Ref 126). The process of applying studs requires careful quality control, particularly when new studs are applied in the field over old, worn-down studs. Lack of fusion at the edge of the weld, or formation of other discontinuities can act as stress raisers that progress into thermal fatigue cracks (Fig. 25). Studs have been burned through the tube during manual application, and the formation of solidification cracks due to the presence of sulfur in the weld pool is also possible when applying studs to a poorly cleaned tube.

Protective Coatings for Carbon Steel Wall Tubes. Some manufacturers and end-users opt to apply a protective coating over the fire-side surface of the carbon steel wall tubes in the lower furnace. A range of alloys and application methods have been used for this purpose, most of which would now be considered obsolete. These coatings fail over time because the porous coating structure allows gases to penetrate to the carbon steel substrate. Newer coatings are generally specified on the basis of as-applied coating density and coating thickness. They are often applied with an automated high-velocity oxyfuel (HVOF) or equivalent technique. Alloy 625 or nominal 50%Cr-50%Ni material are common choices for recovery boiler coatings, but the alloy choice is generally less important than the method of application and level of care taken prior to and during spraying. For the most part, these coatings are applied as an alternative to complete wall replacement where rapid corrosion has occurred. Since they are almost always field-applied under adverse working conditions, coating quality can be variable, and spalling is

Fig. 24 Cross section through a studded carbon steel boiler tube, showing reduction in dimensions of the studs that occurs in operation. Note the loss of wall thickness in the tube around the entire fireside circumference, including the crotch of the tube near the membranes.

Fig. 25 Micrograph showing a thermal fatigue crack that originated at a discontinuity in the base of a stud on a carbon steel tube. The crack has turned and begun to propagate into the thickness of the tube.

frequently encountered (Fig. 26). With stringent quality assurance/quality control in place, and the use of fully automated application, coating lifetimes of 5 to 10 years have occasionally been achieved with only minor annual touch-ups required.

Pack cementation coatings have also been applied to large boiler wall panels (Ref 127). This process leaves a thin, corrosion-resistant layer of nearly pure chromium on the surface of the tubes (Fig. 27). Several boilers have been built with chromized lower furnace walls with favorable, long-term performance reported by the mills. As with other coatings, quality control and assurance are critical to obtaining a consistently uniform product, particularly when dealing with large panels, or panels that include complex shapes and bends. As one example, the chromizing process by nature leaves porosity in the surface known as Kirkendall voids. Under ideal conditions, these voids are found near the surface and do not affect the integrity of the chromized coating. However, improper processing can cause these voids to form as low as the interface with the carbon steel, leaving a potential migration path for sulfur to the underlying carbon steel. Uneven coating thicknesses and poor adhesion between the chromized layer and the underlying steel are other problems that can arise during the manufacturing process.

Composite Tube Construction. Beginning in the mid-1970s, the industry began a transition toward the use of composite tubes in the lower furnace as an alternative to carbon steel tubes. This change has been extraordinarily successful and was the key technological innovation that permitted operation of kraft recovery boilers at steam pressures greater than 8.3 MPa (1200 psi). Composite tubes are made with a corrosion-resistant outer layer metallurgically bonded to an inner core of carbon steel. The vast majority of composite tubes in service are coextruded, with an outer alloy layer formed over an inner core of A210-A1 carbon steel (CS), but some are

Fig. 26 Spalling of a plasma sprayed coating as a result of poor surface preparation prior to the application of the coating

produced via a weld overlay process—either spirally welded around the entire tube circumference, or applied as a one-sided weld overlay on carbon steel panels. Stainless steel type 304L/CS (30403) was the first alloy chosen for use as a composite tube in kraft recovery boilers, and 304L has largely been the material of choice since then, although other alloys are also now used (Table 13). These include proprietary variants of alloy 825 and alloy 625. Ferritic stainless steel weld overlays with between 18 and 25 wt% Cr are used in Japan (Ref 128) and in South America, but have no extensive history in North America or Europe.

Composite tube panels are usually built with a membrane construction, much as for carbon steel walls and floors. Depending on the boiler manufacturer and the date of construction, the membranes between tubes can be solid stainless alloy, roll clad alloy on carbon steel, or weld overlay on carbon steel.

While composite tubes solved nearly all of the problems that affected carbon steel tubes in the lower furnace, particularly those related to gas-phase corrosion, two new issues were introduced when they came into service: preferential corrosion of the external alloy layer and cracking that originates from the fire-side surface. In both cases, the introduction of composite tubes revealed aspects of the corrosiveness of the lower furnace boiler environment that had been completely unsuspected when carbon steel was the material of choice.

Preferential corrosion of the external layer is a particular problem with 304L/CS composite tubes, but has also been observed for composite tubes made from most other alloys, including alloy 625/CS. Surprisingly, once the underlying carbon steel is exposed, it is common for very little corrosion of exposed carbon steel to take

Fig. 27 Cross-section photograph through a chromized tube. The chromized layer (between 0.2 and 0.4 mm thick) contains about 40 wt% Cr at the surface and about 16 wt% Cr at the diffusion boundary with the carbon steel. The voids near the surface are normal artifacts of the chromizing process, and do not affect the corrosion resistance of the coating unless they provide a migration path to the carbon steel surface.

place until the exposed area is quite large. "Balding" was first observed at the corners of air-port openings, on the cold side of the tubes in hidden areas behind flat studs and cast inserts (Ref 129). Subsequently, similar preferential corrosion has been observed at primary air-port openings further around the tube circumference toward the fire-side crown (Fig. 28), as well as on the cold side of the tubes behind insert plates in liquor gun, secondary air port, and burner openings, and on the cold side of the tubes underneath the smelt spout openings, where they are shielded by the smelt hoods.

Neither field observations nor laboratory experiments have clearly established the corrosion mechanism, but this may simply be because there is more than one mechanism operating, depending on the location in the boiler. The generally accepted mechanism for the cold-side corrosion is condensation of sodium hydroxide fumes from combustion gases (Ref 129). Preferential corrosion toward the fire side of the tubes is more likely to be caused by exposure to wet liquor or hydrated sodium sulfide, as formation of NaOH is not thermodynamically favored and alloys that should be resistant to attack by NaOH corrode in these locations (Ref 130). Laboratory corrosion tests in hydrated sodium sulfide/sodium hydroxide produce alloy rankings consistent with most of the field observations (Fig. 29). One effective solution to "balding" at the corners of air-port openings is to ensure that cast inserts are well-sealed with refractory when they are first installed, and to follow up regularly on maintenance outages with restoration of degraded refractory seals. A variety of weld repair methods have been employed, with caution, to restore the protective alloy cover

when concerns existed about corrosion of exposed carbon steel. For the most part, either 309 stainless steel or alloy 625 has been chosen as the filler metal, with mixed success reported for each.

Occasionally, corrosion at the crown of composite tubes has been observed around the level of the primary air ports, and in the lower parts of the spout openings that are subject to washing by the molten smelt leaving the boiler. In the latter case, 304L/CS composite tubes that form spout openings are often replaced with ones made with alloy 825/CS for improved resistance to both corrosion and cracking.

The second issue that affects the use of composite tubes in recovery boilers is cracking of the external corrosion-resistant layer and propagation of these cracks into the underlying carbon steel. Cracking in composite tube panels occurs in many locations, including on the crown of tubes, near the membrane-to-tube weld, in the membrane itself, and at membrane terminations for port openings (Ref 131). The mismatch in thermal expansion coefficients between the alloys used to make composite tubes can be significant, particularly when 304L is used as the outer layer. Consequently, stresses induced in the tubes due to thermal fluctuations were originally considered to be the root cause of cracking in composite tubes. The true situation is actually much more complex, and a number of mechanisms are now known to contribute to the problem, depending on where the cracks form (Ref 132, 133).

Cracking at membrane terminations and along welds for sealed air port inserts in composite wall panels is a common problem in recovery boilers. Thermal stresses undoubtedly play a role at these locations. Many of these cracks remain in the membrane, or propagate along the weld and do not progress into the pressure part, but there is always a concern that they might do so (Fig. 30). Cracking in these locations has been minimized by very careful joint and weld design and attention to detail in fabrication. Recent practice has been to replace seal-welded air-port inserts with bolt-on cast inserts to avoid thermal cracking at the welds. This avoids one problem at the risk of

introducing preferential corrosion at the corners of the openings, as described previously.

Cracking of Composite Floor Tubes. Cracking of 304L/CS composite floor tubes is common in nearly every boiler that uses these tubes, to the extent that this alloy is no longer specified for this application. Portions of wall tubes that are exposed to a similar environment (i.e., at or below the normal level of the smelt bed) are also sometimes susceptible to cracking. Cracking often appears as "craze" cracking on the tube crowns, but is also found along tube/membrane welds and in the membranes themselves (Fig. 31). Fortunately, these cracks almost invariably stop when they reach the stainless/carbon steel interface or turn and propagate along it. Over time, several of these latter cracks may join and cause spalling of the stainless layer. Very few, out of many thousands, of such cracks that have been examined, have ever been documented to penetrate into the carbon steel, and all of these were atypical in cause.

The mechanism of cracking remained controversial for many years, but it is now generally agreed that the root cause of most composite floor tube cracks is stress-corrosion cracking (SCC) that occurs underneath piles of residual smelt during boiler water washes (Ref 132).

Fig. 28 Preferential corrosion of the 304L stainless steel layer in a composite tube. Corrosion occurs at the edge of the bolt-on casting in a primary air port and extends out toward the fire-side crown of the tube

Boiler water washes are performed periodically to clear the superheaters and boiler banks of deposits that plug the gas passages. Depending on the needs of a particular boiler, they may occur anywhere from once annually to six or more times a year. Although the smelt bed is burned down and allowed to cool before washing the boiler, large piles of frozen, but still very hot, smelt are often left in place on the floor. The residual heat in these piles is sufficient to maintain the underlying tubes in a temperature range found appropriate for SCC. Small amounts of water flowing underneath these piles of smelt will quickly form concentrated "soups" or poultices of hydrated salts on the surface of the tubes.

Key observations that have led to this conclusion are:

- Measurements of tube surface temperatures during operation revealed that thermal cycling of the tubes does not correlate with the location of cracking, nor was the magnitude and frequency of thermal cycling sufficient to induce fatigue cracks in 304L.
- Modeling and measurement of residual stresses in composite tubes show that the outer stainless layer is in compression during normal operation, but surface stresses become tensile at about 200 °C (390 °F) as the tube is cooled toward ambient.
- It was found that 304L and other alloys are very susceptible to SCC when exposed to hydrated salt mixtures (Na_2S , NaOH , and Na_2CO_3) that simulate the poultices present on the tubes at temperatures in the range of 160 to 200 °C (320 to 390 °F) (Fig. 32).

Remedial measures that have been adopted for floor tube cracking include monitoring the cracks over time and then grinding the cracks out and repair welding as necessary, or by replacing 304L/CS composite tubes with either studded carbon steel tubes or composite tubes made with

alloy 825 or alloy 625 external layers. A very few mills report no cracking of the 304L/CS composite floor tubes in their boiler, but these mills invariably follow stringent procedures designed to completely burn down the remnant bed on the floor before beginning the water wash or never water wash the boiler.

Cracking of Composite Wall Tubes at Openings. Tubes that form port openings in composite tube walls are also susceptible to cracking in-service, especially at the primary air port and spout openings (Ref 134). Cracks found in these locations include the familiar craze cracks found in floor tubes, as well as single, circumferentially oriented cracks. Unlike the situation for floor tubes, several cracks in tubes that form primary air-port openings have propagated into the carbon steel and tube leaks have resulted from cracking. Cracking at primary air-port openings is generally confined to the two tubes that form either side of the opening, and cracks are nearly always found only in the lower half of the opening. Most cracks are found on the tube bends, but some appear 150 mm (6 in.) or more below the level of the membrane termination (Fig. 33). A strong correlation has been made between frequent, high-magnitude thermal cycles on the air-port opening tubes and cracking, leading to the conclusion that corrosion fatigue is an operative mechanism along with SCC.

Substantial evidence has been accumulated to show that cracking of composite tubes at primary air-port openings occurs as a result of a complex interplay between air-port design, construction practices, boiler operation, and tube metallurgy. Consequently, although boilers from nearly all manufacturers have had cracked tubes at primary air-port openings, not all boilers are affected. Long-term boiler trials have demonstrated that the thermal fluctuations at port openings can be calmed by careful optimization of boiler operation and that the severity and number of cracks is substantially diminished as a result (Ref 135). From a metallurgical viewpoint, laboratory tests have shown that cold-worked alloys appear

much more susceptible to cracking than those that have been annealed (Fig. 34).

Cracking at primary air-port openings has been controlled by a combination of optimizing boiler operation, replacing 304L/SC composite tubes with either alloy 825/CS co-extruded or 625/CS weld overlay tubes and changing the air-port design to reduce stresses induced by manufacture and optimize air flow through the opening (Ref 136). Optimized boiler operation appears to be a critical step in preventing

Solid circles are data points for specimens that failed during the test. Open circles are for specimens that either cracked, but did not fail during the test, or did not crack at all.

Fig. 34 Resistance of alloys to stress-corrosion cracking in hydrated 75% Na_2S -25% NaOH (dry wt%) hydrated salt mixture at 180 °C (355 °F) for a period of 48 h

cracking. None of the other options by themselves have proved sufficient to ensure that cracking will not occur. Alloy 825/CS wall tubes have provided exceptional service in many mills, although cracking of this alloy in tubes that form primary air-port openings has occurred in at least one boiler. Coextruded alloy 625/CS tubes have experienced extensive cracking in a boiler when used as air-port opening tubes.

Cracking of 304L/CS composite tubes in spout openings has generally been controlled by replacing the tubes that form the openings with ones made from alloy 825/CS composite tubes. Small incipient cracking is still often found in the alloy 825/CS tubes, but has been easily controlled by inspection and light grinding as part of regular maintenance. Corrosion of the alloy 825 also occurs where it is exposed to flowing smelt, but at a lower rate than for 304L. Coextruded alloy 625/CS tubes have experienced extensive cracking when used as a spout opening tube.

Smelt Spouts and Air-Port Castings. Smelt spouts guide the molten smelt out of the spout opening in the boiler wall and let it drop into a dissolving tank located underneath the boiler. They are water-cooled, due to the intense heat to which they are subjected from the flowing smelt. In some designs, the end of the spout is butted against the outside of the boiler wall, while in other designs, the spout intrudes into the spout opening to protect the tubes from flowing smelt. Although not a pressure part, corrosion of spouts has contributed to leaks of water into the furnace cavity (Ref 118). Consequently, operating guidelines for kraft recovery boilers generally call for the spouts to be replaced during the annual maintenance shutdown, regardless of their physical condition. For this reason they are generally built from carbon steel. In most boilers, this material provides adequate service. In order to extend the lifetime of spouts, and to prevent premature failure, water-cooled spouts are sometimes clad with corrosion-resistant alloys such as alloy 625 or have had chromized coatings applied, but there has been little systematic study of the value of these approaches to life extension. Proprietary dry spouts, with no water cooling, have been cast from different alloys, including variants of a 50Cr-50Ni alloy.

Corrosion of the cast inserts in primary air-port openings is a maintenance problem in that the flow of primary air into the boiler can be adversely affected by damaged castings, and localized corrosion of composite tubes at the corners of the air-port openings has been linked to poor sealing between the casting and the tube that forms the opening (Fig. 28). Most often these castings are made from ductile iron, but occasional attempts have been made to use different alloys, also including a 50Cr-50Ni alloy.

Mid-Furnace Corrosion

The mid-furnace is a transition zone between the reducing conditions found in the lower

furnace and oxidizing conditions more typical of boiler flue gases. Traditionally, construction of the boiler walls has been of carbon steel, and few corrosion problems were reported. When composite tubes were introduced, the height of the cut-line between the composite walls and the carbon steel walls was established at a level above the secondary air ports. This decision was based on historical corrosion patterns of the time. Over the years, the height of the cut-line has been raised and was eventually "standardized" at about 1 m (3 ft) above the tertiary air-port openings. This has now proved to be insufficient to cope with modern boiler design and operating practices. Many boilers now experience what is known as "cut-line corrosion," or corrosion of the carbon steel tubes beginning at or just above the butt weld between the two types of tube (Fig. 35). In some boilers, the corrosion has been localized to within a few inches of the butt weld, while in others, corrosion of the carbon steel tubes has continued for some distance upward from the weld. Investigation has shown that the environment close to the wall is rich in H_2S , as well as organic sulfur species such as CH_3SH , and that the gas phase cycles continuously between oxidizing and reducing conditions, both of which are known to significantly increase corrosion rates of carbon steel (Ref 137). While the conditions necessary to promote accelerated fire-side corrosion clearly exist in mid-furnace regions, it is still not understood why corrosion would be concentrated so close to the butt weld in some cases and go well up the wall in others. Solutions to mid-furnace corrosion are relatively straightforward—use tubes with a thicker corrosion allowance, apply protective coatings over the corroded carbon steel, or extend the composite tube cut-line to higher elevations in the boiler.

Corrosion of Superheaters

Corrosion of superheater tubes is the Achilles heel of a recovery boiler and limits the overall energy efficiency that can be achieved. This is because the surface temperature of the tubes begins to come very close to the first melting point of deposits that form on the surface of the tubes (Ref 138). Most recovery boilers are designed for flue gas furnace exit temperatures of 950 to 980 °C (1740 to 1800 °F), but actual operational values may be as much as 200 °C (360 °F) lower. By the time the flue gas reaches the boiler bank, nominal temperatures are 600 to 650 °C (1110 to 1200 °F). Depending on the composition of the deposits, the first melting point will vary from about 500 to 600 °C (930 to 1110 °F), with a typical value of about 560 °C (1040 °F) in boilers with limited chloride and potassium inputs to the liquor. Both of these elements are commonly found in superheater deposits. They each have strong influences on the melting behavior of salts in the superheater, although their individual effect is quite different (Ref 139). When chloride is present in a deposit,

a further increase in concentration does not change the first melting point of the deposit—only the proportion of liquid phase in the deposit at the first melting point (Fig. 36). Conversely, the proportion of liquid phase in the deposit at the first melting point does not change at all with increasing potassium content, but the first melting point will decrease substantially (Fig. 37). To ensure that molten deposits are not in contact with the tube surfaces, current boiler designs typically limit superheater steam temperatures in high-pressure recovery boilers to a maximum of

Fig. 35 Thickness profile of a carbon steel tube at the cut-line with the composite tube lower furnace walls

Fig. 36 Influence of chloride (at fixed potassium content) on deposit first melting temperature (Ref 139)

Fig. 37 Influence of potassium (at fixed chloride content) on deposit first melting temperature (Ref 139)

about 480 °C (900 °F) to allow for temperature gradients across the tube thickness. A few boilers already operate at superheater steam temperatures above 510 °C (950 °F), and it is expected that more will be built as companies attempt to maximize energy production (Ref 128).

Relative to other boilers, kraft recovery boilers carry a much higher flux of particulate through the superheater, boiler bank, and economizer sections of the boiler (Ref 112). The composition of the deposits changes substantially as the flue gas passes through the boiler (Fig. 38), and also as a function of how the boiler is operated and the overall dimensions of the boiler. Recovery boilers are specifically built with a tall furnace to increase residence time and ensure complete combustion of the fuel, but entrainment of unburned liquor droplets or droplets in various stages of combustion in the superheaters is a common occurrence, especially in older, overloaded boilers. Plugging of the gas passages in the superheaters and boiler banks is a major operational problem for pulp mills and requires constant sootblowing with steam lances, as well as frequent shutdowns to allow the gas passages to be washed clean with hot water. Modern, well-controlled boilers are generally able to run between annual maintenance shutdowns without needing a water wash, but in older boilers, or boilers with high fuel loads, as many as five or six water washes might be required annually. Any of these operational issues can influence the location and severity of corrosion in the superheaters.

Dramatic changes have been made to boiler operation since 1980 to meet the demand for greater efficiency, higher throughputs, and reduced stack emissions, and these have had a major effect on the environment in the superheater. Total reduced sulfur (TRS) and SO₂ concentrations in the flue gas are now much lower than in the past, while the amount of condensed sodium carbonate fume has significantly increased. Altogether, these changes make the superheater environment much less corrosive. In the past, many superheater corrosion problems were often caused by acidic sulfate deposits containing sodium and potassium bisulfate and pyrosulfate salts—all of which are liquid at superheater tube temperatures (Ref 118). Under modern operating conditions, these acidic sulfates no longer form in sufficient concentrations to cause corrosion, due to the low SO_x concentration in the flue gas and because any that are formed are quickly neutralized by the available sodium carbonate. Locally reducing conditions—formed under droplets of unburned liquor that are carried into the superheaters and impact the tube surfaces—have also been responsible for corrosion of the hotter superheater bends, but this problem is also largely of historical interest, except perhaps for older recovery boilers.

Materials used for superheater tubes in kraft recovery boilers are generally governed by the same design constraints as for other types of boilers, including the need for strength at temperature and good creep resistance. Ferritic

alloys T11 (K11597) and T22 (K21590) are commonly used for superheater tubes in lower pressure recovery boilers, while T91 (K90901) sees service in higher pressure boilers (see Table 12). In boilers with particularly aggressive environments, the hottest superheater bends have been specified in corrosion-resistant austenitic alloys, including 347H (S34709), 310H (S31009), alloy 800 (N08800), and alloy 825 (see Table 12). Coextruded TP310H/T22 tubes have also been used in some boilers. For high-pressure recovery boilers, with superheater tube temperatures significantly higher than 500 °C (930 °F), chloride and potassium removal from the process becomes a critical part of corrosion control. Even so, more corrosion-resistant alloys might be required. Experience reported from Japanese boilers operating with a superheater steam temperature of about 500 °C (930 °F) has

been positive with a proprietary alloy that contains about 25 wt% Cr, except when high sulfur auxiliary fuel was burned in the boiler (Ref 128).

Boiler Bank and Economizers

Flue gas temperatures in the boiler bank quickly fall below the first melting point of the deposits, and consequently the environment is generally not very corrosive. Carbon steel tubes are standard in this part of the boiler and lifetimes of 25 to 30 years for the tubes are common. However, this part of the boiler has not been entirely trouble-free. Throughout the 1980s, many two-drum recovery boilers experienced a particular form of localized corrosion called “near-drum thinning” (Ref 140). This phenomenon involved wastage of the tubes adjacent to the tube seat in the mud drum (Fig. 39). Typically, only small areas around the tube circumference were affected, usually at ten and two o’clock with respect to the direction from which the sootblower passed by the drum at any given tube location. Corrosion rates typically varied between 0.13 and 0.51 mm/yr (5 and 20 mils/yr), although some boilers experienced much more rapid corrosion. The mechanism was determined to be formation of liquid sodium bisulfate underneath deposits on the tube surface. The corrosion process was cyclic—every time the sootblower closest to the drum operated, deposits and corrosion product were removed from the surface of the tube, leaving the process to start over again. As in the superheater sections, process conditions no longer favor the formation of sodium bisulfate, and this type of corrosion is now only rarely encountered and then only in older boilers that still fire low-solids liquor and cannot maintain hot enough beds to generate the necessary sodium carbonate fume in the flue gas. Other design-specific problems that have been encountered in this area of the boiler are corrosion fatigue at header welds and dew-point corrosion of economizer tubes.

Corrosion Control in Air Quality Control

Craig Reid, Acuren

For many years kraft pulp mills have collected and disposed of "foul" condensates and odorous noncondensable gases (NCGs) containing hydrogen sulfide and reduced organic sulfur compounds in order to reduce the impact of emissions on neighboring communities and the environment. These compounds are collectively described as total reduced sulfur (TRS). Typically, low-volume high-concentration (LVHC) gases and off-gases from the stripping of foul condensates are collected at concentrations above their upper explosive limit (UEL) and incinerated in the lime kiln, recovery boiler, power boiler, or dedicated thermal oxidizer. The stripped condensate is recycled within the process and/or sent to the effluent treatment system of the mill. Heat recovered from the gases and condensates is used to heat process water. Some high-volume low-concentration (HVLC) gases are collected below their lower explosive limit (LEL) and incinerated, while others are released to the atmosphere.

In recent years, environmental regulations have progressively restricted the release of TRS and other compounds in NCGs and foul condensates. Accordingly, there has been continuous evolution of processes and process equipment for collection and disposal of NCGs and foul condensates (Ref 141–154).

On Nov 14, 1997 the U.S. Environmental Protection Agency (U.S. EPA) issued the National Emissions Standards for Hazardous Air Pollutants (NESHAP) for selected pulp and paper categories. These new regulations required the collection and disposal of dilute NCGs and condensates from sources that previously were released to the environment by most mills. Depending on the age and process configuration of a mill, these sources may include:

- LVHC vents
- Knotting and screening
- Brown stock washing
- Brown stock decker
- Oxygen delignification
- Weak black liquor storage tank vents

Existing mills can thus end up with two or more parallel systems to collect and dispose of NCGs and strip and recycle foul condensates. It is also apparent that process evolution will continue. Table 14 lists sources of odors and odor-removal uses.

Materials of Construction

Carbon steel is not suitable for NCG collection systems. Concentrated NCGs are saturated

in water, and thus condensation occurs in the collection system. Dissolved NCGs in this condensate make it corrosive to carbon steel. Fiberglass-reinforced plastic (FRP) is generally not recommended for NCG collection systems because of attack on the resin by turpentine and methanol in the NCG system. The FRP resins are also subject to failure should NCG ignite.

Types 304L (S30403) and 316L (S31603) stainless steels have been the materials of choice for process equipment and piping handling NCGs and foul condensates. They do not experience general corrosion and remain free of fouling, which is beneficial for heat-transfer equipment.

Design of collection systems is important. Pipe networks should be properly grounded and potential sparking sources eliminated. Provisions should be made to prevent carryover of black liquor droplets into the NCG piping, especially where the black liquor has significant chloride ion content. Pipe slope should be adequate to ensure rapid condensate flow, and condensate separators should be installed at the low points of the lines (Ref 150). It may also be necessary to purge some lines and equipment on start-up and/or shutdown.

The pH of foul condensates is generally above 8, but in vapor space condensates the pH can be acidic due to dissolved NCGs. Depending on the mill and processes involved, chloride ions may be present. Preferential corrosion of weld metal may occur in the presence of some condensates if they are allowed to collect in "dead" zones. For example, Fig. 40 and 41 show corrosion of ferrite in type 316L weld metal after 20 years of service. Depending on temperature, stress-corrosion cracking of types 304L and 316L has also occurred.

Table 14 Sources of odors and removal units

Removal units	Sources of kraft mill odors
Lime kiln	Digesters
Power boiler	Accumulators
	Electrostatic precipitators
	Contaminated hot water
	Dissolving tanks
	Bleach plant towers
	Washers
	Tailings
	Oxygen delignification
Recovery boiler	Digester relief
Thermal oxidizer	Multieffect evaporators
	Makeup
	Sewer
	Causticizing
	Slaking
	Screens
	Foam tanks
	Brown stock washers and decker
	Digester blow tanks
	Direct contact evaporators
	Sewer outfall
	Mud filters
	Knotters
	Driers
	LVHC vents
	Liquor storage tanks
Wet scrubber	

It is not known if sulfur compounds have played a role in the instances of weld metal corrosion or stress-corrosion cracking. Further, the collection and analysis of NCGs and condensates for diagnosis of corrosion problems is not straightforward, and results may vary depending on sampling and analysis procedures. Thus it is not generally possible to predict which areas of process equipment, if any, may experience corrosion or stress-corrosion cracking. Duplex stainless steels, higher alloy austenitic stainless steels, and nickel-base alloys have been used in response to local occurrences of stress-corrosion cracking.

Stainless steels and nickel-base alloys suitable for high-temperature service are commonly used for burner components for firing NCGs in lime kilns and for some components of dedicated thermal oxidizers (lime kiln materials are discussed in the section "Corrosion Control in Chemical Recovery"). Very aggressive environments from sulfur compounds in the NCGs can develop in thermal oxidizers, which incorporate a quench chamber and scrubber for the combustion gases. Extensive use of nickel-base alloys and type 317L (S31703) stainless steel has been reported.

Because of the wide variety of processes and environments involved in collecting, processing, and incinerating NCGs, it is important when selecting equipment to review past performance and determine if process conditions will be outside the envelope of experience. In all cases, it is desirable to ensure quality in welding to maximize the margin against corrosion or fatigue.

Wastewater Treatment Corrosion in Pulp and Paper Mills

Randy Nixon, Corrosion Probe, Inc.

Corrosion problems are typically more severe in pulp mill wastewaters, especially for bleached pulp mills, than in paper mill wastewaters. These problems are present in wastewater from kraft pulping, sulfite pulping, and thermomechanical pulping (TMP) mill processes. Each of these is discussed in earlier sections of this article. The corrosion problems encountered include oxygen-driven pitting corrosion of submerged carbon steel, vapor phase acidic attack of concrete, microbiologically influenced corrosion (MIC) of carbon and austenitic stainless steels (liquid-phase), liquid-phase chemical attack of concrete, and several other corrosion mechanisms. These mechanisms affect the performance of various components of the wastewater treatment plant process as discussed in this section.

Wastewater System Components and Materials of Construction

The wastewater treatment process in most pulp and/or paper mills consists of two treatment stages:

1. Primary treatment stage, which includes neutralization or equalization and primary clarification
2. Secondary treatment stage, which includes aeration and secondary clarification

Neutralization. When the mill has both acidic and alkaline sewers, it will generally have a neutralization or equalization tank or chamber (generally lined concrete) where the two wastewaters mix and are adjusted for near-neutral pH. This usually includes the addition of sulfuric acid and/or sodium hydroxide. If pH swings are not problematic, it is also common to let the wastewaters mix in the primary clarifiers. The piping materials used for collecting wastewater throughout mills varies widely. Most mills in the United States built their treatment plants as mandated by law in the mid- to late-1970s. At that time, welded carbon steel, fiberglass-reinforced plastic (FRP), precast concrete cylinder pipe, and reinforced-concrete pipe were used. Since that time, much of the collection piping for bleached pulp mills has been replaced or sliplined with FRP or high-density polyethylene (HDPE), respectively, which have performed extremely well.

The primary clarifier provides quiescent flow conditions and retention times where the settlement and removal of suspended solids is accomplished. Most primary clarifiers in mills

are circular concrete tanks with sloped bottoms. A center-supported, motor-driven rake mechanism as shown in Fig. 42 circulates around the tank to push the settled sludge into troughs in the bottom of the tank for conveyance to a sludge thickener or to sludge dewatering equipment. The center inlet column, feed well, baffles, rake arms, and other metallic components are generally constructed from carbon steel coated with a polymer-based coating system, usually epoxy. Type 316 stainless steel has been used in some rake-mechanism replacement projects. This has generally been very successful.

From the primary clarifiers, the clarified wastewater flows through launder troughs and piping to an aeration tank of some kind. The secondary treatment stage now begins.

Aeration. Bacteria are used to cleanse the wastewater biologically by consuming the harmful organic nutrients under oxidizing conditions. This process is largely focused on biological oxygen demand (BOD) reduction and removal. Aeration ensures the health and efficiency of the aerobic bacteria used to metabolize organic compounds and, in the process, converts dissolved solids into suspended solids.

Several types of aeration treatment are used in pulp and paper mills. Trickling filters allow wastewater to be aerated by ambient air while it flows through synthetic media with numerous small openings. Ambient aeration tanks are also used. These large open-topped concrete tanks have piping manifolds in their bottoms that convey compressed ambient air into the wastewater as bubbles. Agitators are used to keep the wastewater well mixed with bacteria and aerated. A third option (used by many Canadian mills) is pure oxygen reactors. These covered concrete tanks provide serpentine-type flow through the use of baffles and include agitators for mixing. Pure oxygen is introduced into the wastewater through piping jets. Since pure oxygen is more efficient than ambient air (20% oxygen), less overall gas flow is required into the wastewater.

Secondary Clarifiers. The overflow from the aeration tanks or chambers goes to the secondary clarifiers. Here the suspended solids created by bacterial action are settled out and removed as sludge. These concrete tanks with metallic rake mechanisms or collectors are generally similar in construction to the primary clarifiers.

Fig. 42 Primary clarifier

The concentration of bacteria in the aeration tanks is maintained by the continuous return of settled biological floc to the aeration tanks from the secondary clarifiers. The return activated sludge (RAS) is a key factor in enhancing BOD removal in the secondary stage of treatment.

The clarified effluent from the secondary clarifiers overflows into the launder troughs and is then commonly discharged. The sludge is either fed back to the aeration tank as RAS or is pumped to a dewatering stage prior to being landfilled or burned in a biomass boiler. Unlike municipal wastewater treatment plants, most pulp and paper mill treatment plants do not use anaerobic digesters to further treat sludge nor do most mills chlorinate the treated wastewater before discharge.

Parameters Affecting Wastewater Corrosivity

Many parameters affect wastewater corrosivity. The most important parameter is pH as it impacts both the corrosion of metals and concrete.

pH. Table 15 (Ref 155) shows different mill wastewater pH ranges for different types of pulp mill and paper mill effluents. Most pulp mills today (2006) neutralize wastewater pH such that the wastewater is less aggressive based solely on pH once the primary clarifiers are reached.

Wastewaters with pH values below about 4 are aggressive to concrete structures and promote higher corrosion rates in carbon steel components. Low pH wastewaters will also affect the corrosion rates of austenitic stainless steels (types 304 and 316) provided high chlorides or other aggressive ions are present. pH values of 6 to 12 are generally not aggressive toward concrete. Rebar corrosion can be sustained in concrete where the pH of the surrounding concrete has been reduced from 12.5 (original) to 9.0, chloride is present, and oxygen diffusion is permitted (Fig. 43).

Chlorides in mill wastewaters generally increase the conductivity of the electrolyte and thus accelerate the corrosion of carbon steels. Higher chloride concentrations promote localized corrosion (pitting and crevice corrosion) of austenitic stainless steels. Localized corrosion of stainless steels is generally limited to collection system (types 304L or 316L) piping and is not found in clarifier components due to the large degree of dilution that occurs. However, chloride

Table 15 Wastewater pH ranges for various pulp and paper effluents

Effluent type	pH range
Kraft pulping (bleached)	2.0–12.0
Sulfite pulping	1.0–4.0
Thermomechanical pulping	4.0–5.0
Alkaline papermaking	7.0–10.0
Acidic papermaking	3.0–6.0

Source: Ref 155

ion ingress into reinforced concrete structures, especially precast, prestressed reinforced concrete piping and inlet structures to treatment plants has caused substantial reinforcing steel corrosion problems in some mills.

Microbiologically influenced corrosion (MIC) occurs commonly in RAS systems causing underdeposit corrosion of carbon steels and stainless steels due to the action of sulfate reducing bacteria (SRB). Uncoated carbon steel and 316L stainless steel have suffered severe corrosion losses due to SRB action in RAS piping systems and in clear effluent piping, respectively (Ref 156). Figures 44 and 45 show carbon steel and 316L stainless steel, respectively, attacked by SRB action.

Where hydrogen sulfide (H_2S) is present in aerobic headspaces or vapor-phase areas in covered wastewater tanks, sulfur-oxidizing bacteria (SOB) metabolize the H_2S and other reduced sulfur compounds to produce sulfuric acid. This biogenic acid formation, common to municipal sewers, causes aggressive corrosion of carbon steel, austenitic stainless steels, and hydrated portland cement. The acid generated by the MIC process causes rapid dissolution of the normally alkaline cement paste that holds concrete together.

Temperature in wastewater systems is typically in the range of 25 to 45 °C (80 to 110 °F) and is not a significant factor contributing to corrosion. When wastewater temperatures exceed this range, however, there can be increased corrosion of carbon steel and stainless

steel. With a high chloride concentration and a wastewater temperature above 60 °C (140 °F), stress-corrosion cracking of austenitic stainless steels can occur. This has seldom been observed in mill wastewater except in some collection piping applications near the source of bleach plant effluents.

Sulfate increases wastewater conductivity and provides nutrition for SRB. Both of those factors contribute to corrosion of metal components. Sulfate attack of portland cement concrete piping and tankage can occur, especially where wetting and drying of the concrete with wastewater is common. Sulfate attack may be found in concert with sulfuric acid attack.

Carbon dioxide (dissolved CO_2) concentrations can be high in mill wastewaters particularly in the covered, slightly pressurized headspaces of pure oxygen reactors. A great deal of CO_2 evolves from the bacterial metabolism of organic compounds during secondary treatment. When aeration tanks are open to the atmosphere, the CO_2 gas largely dissipates into the air. In a covered, slightly pressurized headspace, more of the CO_2 remains dissolved as carbonic acid and the wastewater pH is slightly depressed. This increases the rate of aqueous carbonation attack of hydrated portland cement paste. The dissolved CO_2 concentration appears to have little impact on metal corrosion in mill wastewater systems.

Conductivity clearly contributes to the corrosivity of wastewater as it does in most aqueous environments. For carbon steel or other iron-base alloys, the higher the conductivity, the higher the corrosion rates. This is not necessarily true for stainless steels provided they remain passive and are not subjected to some form of localized corrosion.

Differential aeration influences corrosion in wastewater. For example, aggressive cells are

established between the rake arm surfaces within the sludge layer and those rake arm surfaces above the sludge. The surfaces in the sludge corrode faster than the surfaces above the sludge because of differential aeration and/or concentration effects. These effects increase the open-circuit potential difference between the two regions, one cathodic and the other anodic (Ref 156).

Electrolytic couples (galvanic couples) can also occur between the rake mechanism and the reinforcing steel in the concrete walls and floor of clarifiers. With the two metals in a common electrolyte, the steel (rebars) within the alkaline concrete remain cathodic to the submerged steel rake mechanism and center supports, and so forth. Because there is a large surface area of reinforcing steel, corrosion of the immersed-steel clarifier can be significantly accelerated (Ref 156). Figure 46 shows a rake mechanism that suffered severe corrosive attack.

Velocity also affects wastewater corrosivity. Increased velocity typically increases the corrosion rate of carbon steel and iron-base alloys. An increase in velocity from 0 to 0.08 m/s (0 to 0.25 ft/s) can double the corrosion rate of carbon steel. This effect can occur between the tip of the rake mechanism and the center column of a clarifier.

In summary, many factors contribute to the corrosivity of wastewater, but the most influential parameters appear to be pH, reduced sulfur compound concentration, and velocity.

Corrosion Mechanisms

Numerous corrosion mechanisms occur in pulp and paper mill wastewater systems. The most common mechanisms are discussed separately for metal and concrete substrates.

Metal Corrosion

Corrosion of metals takes several forms in mill wastewater piping and equipment. General corrosion is influenced by pH, dissolved oxygen concentration at the corroding surfaces, conductivity, and velocity. Corrosion rates are

Fig. 43 Effect of pH on corrosion rate of carbon steel rebar in concrete

Fig. 44 Typical carbon steel corrosion morphology due to SRB action

Fig. 45 Resultant leak of 316L stainless steel due to internal SRB activity

Fig. 46 Badly corroded rake mechanism in a primary clarifier

often greater at the center well in clarifiers where dissolved oxygen levels are higher and at rake arm tips where velocities are higher. Experience has also shown that with lower pH wastewater (as in sulfite pulp mills), the corrosion rates of immersed carbon steel components are greater than in more neutral TMP or neutralized kraft pulp mill effluents.

Electrolytic (galvanic) corrosion of immersed carbon steel can occur in areas exposed by local failure of coatings. With typical anodic areas (metal exposed by coating breakdown) being smaller than the cathodic area on coated rake mechanisms, the corrosion rate of the exposed metal can be quite high. Proper recoating of the carbon steel combined with cathodic protection has been very effective in prevention of this rather typical electrolytic corrosion mechanism. Also, replacement of rake-mechanism parts, weirs, baffles, and other components with FRP has been very successful and cost effective.

Microbiological Corrosion. Pulp mill wastewaters often contain high concentrations of sulfur compounds including sulfates. Sulfates are metabolized under anaerobic conditions in wastewater piping to produce dissolved sulfides eventually forming hydrogen sulfide. The SRB involved cause corrosion of carbon steel waste water piping in the collection system. This same mechanism occurs in carbon steel and stainless steel RAS piping systems and in final effluent (clear effluent) piping where biofilm deposits develop and create an anaerobic environment. Once the biofilm prevents oxygen from being present, SRB colonize. As they metabolize the sulfates, enzymes are produced that create acidic conditions beneath the biodeposits and corrosion proceeds. The same corrosion problem is common in carbon steel sludge piping used to convey waste-activated sludge (WAS) from the clarifiers to the dewatering presses or filters.

Replacement of carbon steel wastewater collection and RAS piping with FRP and HDPE has been very successful. Reasonable performance has been attained in valves and pumps for these same systems using type 317 stainless steel; however, other stainless steels more resistant to SRB associated corrosion are being studied. Promising results have been reported for alloy 2205 duplex stainless steel (Ref 157).

Another microbial corrosion problem related to sulfur species involves the metabolism of hydrogen sulfide by SOB in aerobic headspaces of pipes and tanks. Hydrogen sulfide gas evolved from anaerobic sludge layers dissolves in the headspace condensates, and the *thiobacillus* bacteria metabolize the H_2S , ultimately producing sulfuric acid. The sulfuric acid can produce pH levels as low as 1 to 2, resulting in aggressive corrosion of carbon steel, 304 stainless steel, and concrete. This problem has been identified in stainless steel WAS piping, wastewater collection piping, covered tanks, pure oxygen reactor concrete, and in stainless steel agitator shafts in pure oxygen reactors (Ref 157).

Other forms of metallic corrosion mechanisms are rare in mill wastewater systems.

Concrete Corrosion

There are four basic mechanisms of concrete corrosion in mill wastewater systems: acid attack, aqueous or liquid phase carbonation, chloride-related deterioration, and sulfate attack.

Acid Attack. Acids react with concrete in a standard, acid-base neutralization reaction. The most common acid environment in mill wastewater systems is the sulfuric acid formed by bacterial action in aerated headspaces. This biogenic acid attack occurs in vapor spaces and has been discussed previously. Acid attack of concrete also occurs in the liquid phase where manufactured acids depress the pH of mill wastewaters. The rate of attack depends on the types of acids present and their concentrations.

The hardened cement paste in concrete is very alkaline, usually starting out with a pH above 12.5. The cement reacts with acidic solutions to produce soluble salts. These are mostly calcium salts because the hydrated cement is about 25% calcium hydroxide. Acid attack dissolves the cement phase of the concrete away, exposing the less soluble aggregate materials (Fig. 47).

In mill wastewater streams, the typical acids or acid sources are: sulfuric and hydrochloric acids from upsets in ClO_2 production, D-stage bleaching filtrates, and sulfite pulping process streams. Prevention of aqueous acidic attack of concrete has largely been achieved through the use of neutralization tanks and pH adjustment systems for the mill effluents. However, organic linings such as epoxies, polyurethanes, and vinyl esters for tanks have also been effective. Similarly, the biogenic headspace acidic attack has been averted through the use of anchored thermoplastic sheet linings or liquid applied organic linings.

Carbonation of Concrete (Liquid Phase). Carbonation occurs naturally in all concrete exposed to the atmosphere or to carbonated waters. It involves the reaction of carbon dioxide, CO_2 , with the hydrated constituents of portland cement paste, especially calcium hydroxide, $Ca(OH)_2$. In the case of $Ca(OH)_2$, the reaction is:

The reactions are actually more complex, with several reactions occurring between CO_2 and the

Fig. 47 Typical acidic attack of concrete in a neutralization chamber

other constituents of the hydrated cement paste. Regardless, all of these reactions produce carbonates, and they invariably result in shrinkage of the cement paste. Carbonation also occurs in concrete where CO_2 has been absorbed by water, producing carbonic acid.

The rate of carbonation in hardened concrete depends strongly on the permeability of the concrete, which in turn depends on the water-to-cement ratio, wastewater temperature, the concentration of CO_2 (carbonic acid) in the water, and the hardness and alkalinity of the water. Permeable concrete shows a greater rate of carbonation.

Liquid-phase carbonation of concrete occurs widely in mill wastewater treatment plant structures primarily in aeration tanks, oxygen reactors, and primary and secondary clarifiers. It is more common in pure oxygen reactors where greater dissolved CO_2 concentrations are possible due to the pressurized headspaces in these structures (Fig. 48). The CO_2 is generated by the decomposition of organics by aerobic bacteria in the reactors or aerators. Carbonation is also more aggressive where source waters are lower in hardness and alkalinity.

The rate of cement paste attack by liquid-phase carbonation is generally very slow. Usually the carbonation rate is approximately 2 to 3 mm ($1/16$ to $1/8$ in.) of depth loss in the first 1 to 2 years of exposure. Due to the pore-blocking effects of calcium carbonate and water, this rate slows down significantly after the first couple of years, depending on the extent of turbulent flow present.

Cement paste depth losses are typically 13 to 19 mm ($1/2$ to $3/4$ in.) over 15 or so years of exposure. The rate of cement paste loss is strongly influenced by flow conditions. Under quiescent conditions, the rate of attack is extremely low. The high solubility of calcium carbonate makes carbonation especially influenced by flow conditions. In turbulent flow conditions, the rates are much higher as the reaction products are washed away exposing fresh alkaline surfaces for further attack.

Carbonation can be reduced by ensuring high-quality, low-density concrete is used through lower water to cement ratios and proper curing

Fig. 48 Cement paste losses due to liquid-phase carbonation in a pure oxygen reactor for a pulp and paper mill

practices. Protective organic or inorganic linings and sealers are also effective.

Chloride-Induced Concrete Deterioration (Vapor Phase). When a wet concrete mix is placed around steel reinforcing bars, a corrosion reaction occurs between the steel and the alkaline paste to produce a tightly adherent, protective oxide film on the steel surface. This passive film is stable at pH above 11 and prevents corrosion of the steel if the film is not damaged or removed.

Passive protection of the steel can be lost when the pH at the rebar/concrete interface decreases because moisture and oxygen penetrate the concrete and reach the steel. Chloride ions are particularly harmful because they disrupt the passive oxide film on the reinforcing steel (Fig. 49). Penetration can occur slowly by permeation of the concrete or rapidly through crack paths. Penetration usually occurs at different times in different locations to form local corrosion sites (anodes) on the reinforcing steel. The uncorroded, still-passive areas serve as the cathodes.

As the steel corrodes, expansion forces occur within the concrete because the steel corrosion products (rust) have a much greater volume than the steel that corroded to produce them. These expansion forces are much greater than the tensile strength of the concrete cover over the reinforcing steel. The concrete therefore cracks and spalls allowing further ingress of the corrosive environment to the steel to cause further corrosion.

The concrete matrix is not chemically influenced by chlorides. However, concrete exposed to an external source of chlorides can still deteriorate surprisingly rapidly because the presence of chloride ions significantly accelerates the corrosion of reinforcing steel in concrete.

Chloride ions are sufficiently small and mobile to readily enter the concrete and penetrate and undermine the stability of the passive film. This makes it easier for corrosion of the steel reinforcement to start and increases the conductivity of the environment around the steel. This latter effect increases the corrosion rates by enlarging the effective size of the cathodic zone around the corroding, anodic sites and generally increasing the chemical activity of the corrosion reactions.

Fig. 49 Chloride ion induced rebar corrosion in a concrete splitter box that directed flow to two primary clarifiers in a bleached sulfite mill

Once rebar corrosion has started, chloride ions also play a pivotal role in acidifying the local anodic zone environment including the surrounding concrete. This is because iron cations react with water (hydrolyze) to form a solid precipitate of iron hydroxide or rust and produce hydrogen cations and chloride anions—that is, hydrochloric acid. A simplified overall reaction is:

Increased corrosion of the steel due to loss of passivity produces more ferrous cations that eventually form more rust and generate more acid. This lowers the pH and increases the concentration of chloride ions at the steel surface, promoting more corrosion and continuing the destructive cycle.

Chloride-induced reinforcing steel corrosion in wastewater treatment systems occurs in vapor phase areas that are subjected to cyclic wetting and drying conditions. Below the water line, sulfates and other precipitates commonly have a pore blocking effect that retards chloride intrusion and oxygen diffusion into the concrete. In lift stations, collection pipes, and in other chambers that experience varying flow elevations, chloride-induced rebar corrosion can cause severe degradation in a few years. The source of the chlorides can be chloride-rich accelerating admixtures used when the concrete was placed. This is, however, unusual in structures built since 1975 when use of such admixtures were generally stopped based on revised concrete design practices (see American Concrete Institute, ACI, documents 318 and 222R). The usual source of chloride ions in wastewater streams today (2006) is bleach plant effluents. Chlorides may also enter the wastewater stream in coastal mills that process sea floated logs. Mill closure to reduce water use may increase the chloride ion concentration in the mill process streams and thus in the wastewater to be treated.

Chloride ion related concrete degradation can be prevented by the use of dense concrete with adequate concrete cover thickness over reinforcing steel bars, through HDPE sliplining of concrete piping, and through the use of protective organic linings over concrete structures.

Sulfate Attack (Vapor Phase). Sulfate attack is the mechanism where sulfates (SO_4^{2-} , commonly from H_2SO_4) react with certain constituents in hydrated portland cement paste to form reaction products larger in volume than the reactant compounds. This increase in volume produces expansive forces, which can exceed the tensile strength of the concrete and promote microcracking and disintegration of the concrete matrix. When accompanied by water or water vapor allowing penetration into concrete capillary porosity, the sulfate attack mechanism is generally accelerated. Evaporation cycles can

increase the sulfate reactions through the concentration of sulfates in the pores of the concrete.

Sulfate attack appears to be a two-stage chemical reaction. First, the sulfate ion reacts with the calcium ions in hydrated portland cement paste, mainly with calcium hydroxide. This reaction forms calcium sulfate or gypsum:

The second reaction occurs between the sulfate ion of the gypsum and hydrated calcium aluminate (mainly tricalcium aluminate or C_3A) to form calcium sulfoaluminates, mainly tricalcium sulfoaluminate or ettringite:

The most destructive expansion occurs with the second reaction (Ref 158).

Sulfate attack of concrete occurs in sulfite pulp mill effluents and in the equalization tanks where sulfuric acid is used for wastewater pH adjustment prior to primary clarification. It does not appear to be a problem in most TMP or kraft pulp mill wastewaters except where upset conditions have occurred, resulting in higher-than-usual sulfate concentrations in structures where level changes are frequent. Prevention is again achieved through the design and construction of dense concrete, the use of organic linings, or through proper process control upstream of the wastewater treatment plant.

ACKNOWLEDGMENTS

Corrosion in the Food and Beverage Industries

Shi Hua Zhang and Bert Moniz, DuPont Company
Michael Meyer, The Solae Company

A RECENT SURVEY estimated the total annual direct cost of corrosion in the food-processing industry as \$2.1 billion dollars. This cost assumes the stainless steel consumption and cost in this industry are entirely attributed to corrosion (Ref 1). The total estimated stainless steel cost for the food-processing industry is \$1.8 billion per year, accounting for about 86% of the total annual corrosion cost. This cost includes stainless steel utilized in beverage production, food machinery, cutlery and utensils, commercial and restaurant equipment, and appliances. Other annual corrosion costs include \$250 million for the cost of aluminum cans in the beverage industry and \$50 million for corrosion inhibitors used in the food-processing industry (Ref 1). It can be seen from these costs that the appropriate stainless steel selection is the primary method for addressing corrosion problems in the food and beverage industries. As a result, this article focuses primarily on the applications of stainless steels.

Corrosion Considerations

There are several distinct aspects of corrosion that should be taken into account when solving the corrosion problems in the food and beverage industries:

- Stainless steels are the primary material of construction for equipment used in the food and beverage industries due to their high corrosion resistance, cleanability, and sanitization properties. The majority of corrosion problems faced in the food and beverage industries are related to stainless steel. It is essential to understand the corrosion properties and corrosion mechanisms of stainless steels to more efficiently solve corrosion problems in the food and beverage industries.
- Although in general the corrosivity of food-stuffs is less than that of most aggressive chemicals, some foodstuffs are quite corrosive. Factors attributing to the corrosivity of foods and beverages include organic acids

with low pH, moderately to highly concentrated chloride from salt, and the high temperature at which some foods are processed. When selecting materials of construction for food- and beverage-processing equipment, all these factors should be considered and evaluated.

- In the food and beverage industries, small amounts of corrosion that do not detrimentally affect equipment integrity and safety cannot be tolerated due to concern for potential contamination and food spoilage of products by metallic ions.
- Due to the hygiene requirement in food-processing equipment, cleaning and sanitizing are necessary processes frequently performed in any food-manufacturing process. Since some cleaning and sanitizing media are quite corrosive to metals, the selection of proper cleaning and sanitizing agents and the strict control of the cleaning and sanitizing process parameters become some of the critical parts of an overall corrosion-control strategy.
- Some of the processes used in the food and beverage industries, such as cooling water treatments, are similar to those used in other industries, such as in the chemical processing industry. General practices used in these industries for attacking similar corrosion problems may be adopted for use in the food and beverage industries.
- When materials and chemicals (such as corrosion inhibitors) are in direct contact with foods and beverages during manufacturing, processing, and handling, they are regulated and must comply with the applicable regulations.

Regulations in the United States

Materials used in food processing must be certified as "food grade," meaning it is safe for use in food. With polymers and elastomers, food grade implies the product is made from virgin

material; that is, it has not been contaminated or reprocessed.

3-A Sanitary Standards Inc. (3-A SSI) formulates standards and practices for the sanitary design, fabrication, installation, and cleanability of dairy and food equipment/systems that are used to handle, process, and package consumable products where a high degree of sanitation is required (Ref 2).

The dairy industry first developed standards in the 1920s to define its sanitation requirements. 3-A standards exist for 70 different types of equipment, such as heat exchangers, holding tanks, homogenizers, evaporators, gaskets, pumps, and so forth. Conforming equipment may display the 3-A symbol, which certifies the design meets 3-A standards in hygienic design and cleanability. 3-A standards have often been incorporated de facto by other segments of the food industry.

It is difficult to obtain a waiver from 3-A standards. For example, 3-A sanitary piping and pump standards are dominant, because of the sheer weight of experience contained in them. There currently are no 3-A standards addressing equipment or piping corrosion.

The American Society of Mechanical Engineers (ASME) Bioprocessing Equipment (BPE) Code has increasing influence within the industry in aspects of equipment design (Ref 3). It addresses:

- The need for equipment designs that can be cleaned and sterilized
- Special emphasis on the quality of weld surfaces once the required joint strength is obtained
- Standardized definitions used by the entire community from fabricators to end users
- The need to accommodate and integrate other relevant standards into the Code

Bioprocessing equipment covers design for cleanability and sterility, dimensions and tolerances for stainless steel tube welding, hygienic clamp fittings, material joining guidance, stainless and higher alloy materials surface finishes,

and sanitary equipment sealing. The BPE Code follows ASME B31.3 for general piping requirements.

The BPE Code systems may be used for services that contact water, such as water for injection (WFI), purified water, clean steam, and other products.

The American Welding Society (AWS) is becoming increasingly involved in regulating fabrication practices in food and pharmaceuticals, but has developed relatively few standards (Ref 4). When a few large shops used to control the industry there was no need to capture the nuances of fabrication. Smaller, less experienced shops require more guidance, and the AWS standards help with welding procedure guidance. Among these standards are:

- 18.1 Specification for Welding of Austenitic Stainless Steel Tube and Pipe Systems in Sanitary (Hygienic) Applications. It outlines welding standards for use in the manufacture and construction of dairy- and food-product processing plants.
- 18.2 Guide to Weld Discoloration Levels on Inside of Austenitic Stainless Steel Tube. It shows the degrees of coloration on the inside of an austenitic stainless steel tube with increasing amounts of oxygen in the backing shield gas.

The Food and Drug Administration (FDA) through hazard analysis and critical control point (HACCP) follows seven principles (Ref 5):

- Analyze for potential hazards. They could be biological, such as a microbe; chemical, such as a toxin; or physical, such as ground glass or metal fragments.
- Identify critical control points. Indicate places in the production line, from raw state through processing and shipping to assimilation by the consumer, where a potential hazard can be controlled or eliminated. For example, cooking, cooling, packaging, and metal detection.
- Establish preventive measures. Select critical limits for each control point. For example, with cooked food it might include designating the minimum cooking temperature/time to ensure microbe elimination.
- Create procedures to monitor the critical control points. They might include determining how and by whom time and temperature should be monitored.
- Decide on required corrective actions when monitoring indicates failure to meet a critical limit. For example, reprocess or dispose of food if the minimum cooking temperature is not met.
- Write procedures to verify that the system is working properly. For example, testing time-and-temperature recording devices to verify that a cooking unit is performing as required.
- Install effective record-keeping practices, backed by sound scientific knowledge to document the HACCP system. This would include records of hazards and their control methods, the monitoring of safety

requirements, and action taken to correct potential problems. An example of sound scientific knowledge includes published microbiological studies on time and temperature factors for controlling food-borne pathogens.

The HACCP system is based on sound science and focuses on identifying and preventing hazards from contaminating food and permits more efficient and effective oversight. Record keeping allows investigators to assess long-term compliance rather than on the day of an inspection. If there is a potential corrosion problem, HACCP would require a prescription to address it.

The FDA also takes responsibility for determining whether and how manufactured materials may be used in contact with food products. Definitions for proper use are found in a series of regulations published annually under Government Regulations CFR 21 (see discussion below). The FDA provides certain specifications regarding composition, additives, and properties. A material that meets these standards can then be stated as FDA compliant. It is the responsibility of the end user to use the product in a manner compatible with FDA guidelines (Ref 6).

Code of Federal Regulations (CFR) Title 21, Subpart B—Substances utilized to control the growth of microorganisms, Section 178.1001 Sanitizing Solutions, describes sanitizing solutions that may be safely used on food-processing equipment and utensils, and on other food-contact articles as specified in this section, within prescribed conditions.

United States Department of Agriculture (USDA). The USDA has jurisdiction over equipment used in federally inspected meat and poultry processing plants and over packaging materials used for such products. Materials used in this equipment are approved on an individual basis. Determining suitability for use of components and the materials from which they are made is the responsibility of the equipment manufacturer.

Corrosivity of Foodstuffs

The corrosivity of a foodstuff is determined primarily by its fluid pH and the chloride ion concentration. The pH ranges of a number of foodstuffs are shown in Table 1 (Ref 7, 8). Many foods are acidic in nature, and the chloride ion concentration of foods can be as high as a few thousand ppm. Foods such as liquid sugars and gelatin may contain chloride ion on the order of 2000 ppm (Ref 9), while some dairy whey solutions may contain levels very much greater than this (Ref 7). In general, the most corrosive foodstuffs and processes are those containing high chloride levels, high oxygen content, at a low pH, and operating at relatively high temperatures. Most stainless steels provide good corrosion resistance by forming a robust passive film on the metal surface. High chloride ion and

low pH conditions tend to damage the passive film of the stainless steels and initiate localized corrosion, such as pitting. Three factors, pH, chloride, and temperature play an even more important role in determining the corrosion severity when 300 series stainless steels (austenitic stainless steels) are used as the materials of construction. Currently, 300 series stainless steels are widely used in food and brewery industries due to their good corrosion performance. However, two concerns when selecting these stainless steels are their susceptibility to stress-corrosion cracking (SCC) and pitting. Although the SCC of the austenitic stainless steels may be affected by many factors, in general the prerequisite conditions for the initiation

Table 1 Approximate pH values of various foods

Food	pH
Apples	2.9–3.3
Apricots	3.6–4.0
Asparagus	5.4–5.8
Bananas	4.5–4.7
Beans	5.0–6.0
Beers	4.0–5.0
Beets	4.9–5.5
Blackberries	3.2–3.6
Bread, white	5.0–6.0
Butter	6.1–6.4
Cabbage	5.2–5.4
Carrots	4.9–5.3
Cherries	3.2–4.0
Cider	2.9–3.3
Corn	6.0–6.5
Crackers	6.5–8.5
Dates	6.2–6.4
Eggs, fresh white	7.6–8.0
Flour, wheat	5.5–6.5
Gooseberries	2.8–3.0
Grapefruit	3.0–3.3
Grapes	3.5–4.5
Hominy (lye)	6.8–8.0
Jams, fruit	3.5–4.0
Jellies, fruit	2.8–3.4
Lemons	2.2–2.4
Limes	1.8–2.0
Maple syrup	6.5–7.0
Milk, cows	6.3–6.6
Olives	3.6–3.8
Oranges	3.0–4.0
Oysters	6.1–6.6
Peaches	3.4–3.6
Pears	3.6–4.0
Pickles, dill	3.2–3.6
Pickles, sour	3.0–3.4
Pimento	4.6–5.2
Plums	2.8–3.0
Potatoes	5.6–6.0
Pumpkin	4.8–5.2
Raspberries	3.2–3.6
Rhubarb	3.1–3.2
Salmon	6.1–6.3
Sauerkraut	3.4–3.6
Shrimp	6.8–7.0
Soft drinks	2.0–4.0
Spinach	5.1–5.7
Squash	5.0–5.4
Strawberries	3.0–3.5
Sweet potatoes	5.3–5.6
Tomatoes	4.0–4.4
Tuna	5.9–6.1
Turnips	5.2–5.6
Vinegar	2.4–3.4
Water, drinking	6.5–8.0

Source: Ref 7, 8

of SCC are: (a) a mechanism for concentrating chloride, (b) temperatures above 60 °C (140 °F), and (c) a tensile stress within the material, such as residual stress at welds. Pitting may occur in stagnant conditions in waters and when oxidizing chloride-containing solutions are used to clean equipment.

Corrosion in Organic Acids. When organic acids are present, molybdenum-containing type 316 stainless steel offers better resistance to corrosion than molybdenum-free type 304 stainless steel. In general, the corrosivity of organic acids decreases as the carbon chain length of the acid increases. The most corrosive organic acid is formic, followed by acetic and oxalic. Elevated temperatures and the presence of chloride increase attack. Table 2 contains the corrosion-rate data of types 304 and 316L stainless steels in various organic acids (Ref 10).

Some of the other chemical constituents of food fluid can act as corrosion inhibitors. For example, phosphates, polypeptides (proteins), and some anions including hydroxyl, carbonate, sulfate, and nitrate are known to inhibit pitting corrosion of stainless steel in chloride-containing solutions (Ref 7, 11). A recent study (2003) has shown that some of the amino acids have certain inhibition effects on the corrosion of carbon steels in acid environments (Ref 12, 13).

Specific Considerations for Beer and Wine. Beer has a pH of about 4 when fresh, but the pH can drop to 3.5 or below if the beer is exposed to oxygen such that it sours (Ref 14). Stainless steel is generally capable of handling these acidity levels.

In the wine industry, sulfur dioxide is widely used to suppress biochemical action. Sulfur dioxide is the most corrosive agent found in wines as it forms sulfurous acid (Ref 15). In addition, tartaric, acetic, tannic, malic, and citric acids are also found in wines to a greater or lesser extent. Stainless steel is resistant to all these weak acids in the concentration in which they may occur (Ref 15). The selection of the exact stainless steel to use is really dependent on the free sulfur dioxide content in the wine. For example, in Germany, where the free sulfur dioxide content is limited by law to a maximum of about 50 ppm, type 304 stainless steel has been widely used for many years with excellent results. However, it is generally accepted that if the free sulfur dioxide content exceeds about 75 ppm, it is safer to use type 316L stainless steel

(Ref 15). When wine tanks are only partially filled, sulfurous acid droplet condensation may occur on the tank roof and walls in the vapor phase above the wine level at much lower free sulfur dioxide contents and cause pitting at these vapor locations. To minimize the risk associated with these phenomena, it is preferable to fabricate the tank out of type 316L stainless steel.

Contamination of Food Products by Corrosion

Since stainless steel—particularly type 304 stainless steel, which contains 19% Cr and 9% Ni—is widely used both in industry and domestically for the processing and preparation of food, the potential contamination of food products by corrosion of stainless steel has been a concern for a long time. This potential food contamination issue had been addressed as early as 1961 (Ref 15, 16). It was found that when an 18Cr-15Ni stainless steel utensil was used for cooking fruits, vegetables, poultry, rice, and custard for 1 h, the chromium and nickel contents of the foods were found to be 0.12 and 0.13 ppm, respectively. When a stainless steel containing 3.7% Mo was used in another test, the residual molybdenum content was 0.05 ppm. It was concluded, therefore, that the quantities of these elements likely to be found in foods as a result of contact with stainless steel are of no pharmacological significance and that stainless steel alloys most likely to be used with foods or by the food-processing industry are safe.

In a 1997 study (Ref 17), lemon marmalade, green tomato chutney, potatoes, rhubarb, and apricots were cooked from 15 min to 2 h at normal domestic cooking temperature using 12 stainless steel saucepans from four manufacturers. The foods were purposely selected because their acidity or chloride content made them more likely than other foods to be aggressive against stainless steel. The study results showed that using new pans caused a higher nickel and chromium release. For example, the original mean chromium content of rhubarb before cooking was <30 ppb, while the chromium content increased to 202 ppb after cooking using a new stainless steel saucepan. The nickel content of the rhubarb increased from 39 to 296 ppb in the same case. After the stainless steel saucepans were used many times, the chromium

and nickel release rate was decreased drastically, probably due to the passive oxide film formed on the surface. For instance, the chromium content was reduced to 49 ppb after the new saucepan was used for five cooking operations. The nickel content was reduced to 66 ppb in the same case. The surface treatment conditions of the new pans have a significant effect on the chromium or nickel release rate. The new stainless steel saucepans with four kinds of surface treatments including (a) mild abrasion using a stainless steel reviver, (b) treatment with nitric/hydrofluoric acid (HNO₃/HF), (c) electropolishing, and (d) ultrasonic cleaning were used in the test for evaluating surface finish effects. It was found that the electropolished saucepans had the lowest chromium and nickel release rate. The chromium release was reduced about five times by electropolishing treatment, from 202 to 40 ppb. The HNO₃/HF treatment resulted in the smallest improvement, as the results were unclear (appeared to be random in nature). The chromium content was increased from 202 to 250 ppb, while the nickel content was reduced from 296 to 90 ppb after the HNO₃/HF treatment. In all experiments the ratio of chromium to nickel in the food product was less than 2 to 1, the ratio of the concentration of these metals in the stainless steel. This suggests the acids in fruits react preferentially with nickel. The study showed that although chromium and nickel pickup due to the use of stainless steel utensils was evident, the amount of the chromium and nickel pickup may not be significantly high compared to the daily intake from the diet and water. The daily intake of chromium from the diet and water has been reported as 50 to 200 µg/day (Ref 17, 18), and average human daily intake of nickel is approximately 200 µg/day (Ref 17, 19).

In the wine industry, the potential contamination of wines, particularly by iron ions, through the corrosion of stainless steels had been extensively studied before stainless steels were popularly used in the industry. Tests made by the Services Technique du Comité Interprofessionnel du Vin de Champagne showed that over a 4 year period, there was no difference in iron content between wine stored in a stainless steel tank and the same wine stored in corked glass magnums (Ref 15, 20). A number of tests carried out in several countries including Germany, France, and Switzerland showed that there was no difference in the iron content and the turbidity between wine in contact with stainless steel and wine in contact with the more traditional equipment, such as concrete and glass-lined tanks (Ref 15). The good performance of stainless steels in the wine industry has been confirmed by experience.

Selection of Stainless Steels as Materials of Construction

Selecting the most appropriate materials of construction for food-processing equipment is

Table 2 Comparative corrosion resistance of type 304 and type 316L stainless steel

Solution	Temperature		Corrosion rate			
			304		316L	
	°C	°F	mm/yr	mils/yr	mm/yr	mils/yr
20% acetic acid	Boiling	Boiling	0.76	30	0.007	0.3
10% citric acid	99	210	0.21	8.3	0.13	0.5
45% formic acid	Boiling	Boiling	1.22	48	0.28	11
65% nitric acid	Boiling	Boiling	0.18	7	0.20	8
10% oxalic acid	Boiling	Boiling	1.22	48	0.91	36
0.4% hydrochloric acid	27	80	0.25	10	0.130	5
40% sodium bisulfide	Boiling	Boiling	0.041	1.6	0.028	1.1

Source: Ref 10

the most effective method for addressing/preventing potential corrosion problems in the food and beverage industries. The processing equipment must have good corrosion resistance to foodstuff without contamination, and it must survive cyclic cleaning and sanitizing processes. Stainless steels have been the most popular and widely used materials of construction in the food and beverage industries due to their excellent general corrosion resistance, reasonably good pitting and crevice corrosion resistance, cleaning ease, and appealing appearance. A discussion of specific stainless steels, their corrosion resistance, fabrication and applications is presented in this section, and compared to other potential materials of construction.

Stainless Steel Types. Although there are several families of stainless steels (Ref 21), the austenitic family is by far the most widely used and the ferritic family is sometimes used. Chromium and nickel are the predominant alloying elements. For example, the most popular austenitic stainless steel, type 304 (UNS S30400), contains about 18% Cr and 8 to 10% Ni. The alloying elements play an important role in offering different corrosion resistances to stainless steels. In general, chromium will promote the passivation of stainless steels and increase the corrosion resistance of steels in oxidizing environments. Nickel usually promotes corrosion resistance of steels in reducing environments. Molybdenum, an element sometimes added to stainless steels, increases resistance to localized corrosion, such as pitting and crevice corrosion. An example of a molybdenum-containing stainless steel is type 316 (S31600).

The austenitic stainless steels offer excellent general corrosion resistance, good pitting, and crevice corrosion resistance with ease of fabrication and weldability (Ref 22). Although all kinds of localized corrosion, such as pitting, crevice corrosion, and intergranular corrosion could occur under certain environmental conditions, the most insidious corrosion form that austenitic stainless steels are extremely susceptible to is SCC. Stress-corrosion cracking is a cracking process that requires the simultaneous action of tensile stress and a specific corrosive environment and leads to an early failure of the steel (Ref 21, 23). In the case of 300 series stainless steels, practical experiences and experimental tests show the prerequisite conditions for the initiation of SCC include:

- The existence of some tensile stress. This can be caused by either a residual stress from the manufacturing processes or stress developed during normal operating conditions.
- Corrosive environment. Chlorides are present in tens of ppm. However, any conditions that generate local concentrations of chloride, such as condensation and alternate wet-dry areas, make the situation even more severe.
- Temperature. The threshold temperature above which SCC may occur is normally 50 to 60 °C (120 to 140 °F) (Ref 22, 24).

Although the elimination of one of these conditions would minimize or stop SCC, it is not practical to do so in most engineering applications. A more practical option for solving SCC is to select or change the material of construction so that it is not susceptible to SCC.

A typical ferritic stainless steel is type 444 (S44400), which contains 18% Cr, 0.5% Ni, 2% Mo, and carbon as low as 0.025%. One of the advantages of ferritic stainless steel is immunity to SCC, while the resistance to pitting and crevice corrosion is comparable to that of type 316 stainless steel in most environments. Due to a relatively high ductile-to-brittle transition temperature, it is recommended that the maximum thickness of type 444 ferritic stainless steel that can be satisfactorily welded is 3 mm (0.125 in.).

A third family of stainless steel that finds increasing favor in food processing are the duplex stainless steels, which contain approximately equal amounts of ferrite and austenite in their microstructure. The advantages of duplex stainless steels include a high strength (stronger than carbon steels and austenitic stainless steels), good general corrosion resistance and pitting/crevice corrosion resistance, and very good SCC resistance compared with austenitic stainless steels. An example of a duplex stainless steel is 2205 (S31803), which contains 22% Cr, 5% Ni, 3% Mo, and a maximum carbon content of 0.03%. One concern with duplex grades is that they very easily form brittle intermetallic phases. For this reason, the maximum recommended service temperature for duplex stainless steels is about 315 °C (600 °F).

Basics of Stainless Steel Selection. Selecting materials of construction for food and brewery processing equipment normally begins with type 304L (S30403) stainless steel. When an environment is more corrosive than 304 stainless steel can withstand, the material is usually upgraded to type 316L (S31603) stainless steel to improve its pitting and crevice corrosion resistance. When an environment becomes extremely aggressive, the material may need to be upgraded to a more corrosion-resistant superaustenitic stainless steel, such as AL-6XN (N08367), which contains high level of chromium (20%), nickel (24%), and molybdenum (6%). If chloride SCC of a 300 series stainless steel occurs, other stainless steels, such as ferritic or duplex stainless steels, may be chosen to reduce or eliminate SCC. In some cases, the selection of more expensive nickel-base alloys is necessary if the processing conditions are extremely corrosive.

Joining Stainless Steels. The general rules for fabricating austenitic stainless steel equipment include (Ref 25):

- Always use high-purity inert welding gases and cover gases to protect the welding zone from oxidation.
- If two surfaces are tack welded to hold them in place prior to making the primary weld, ensure the tack welds are well purged with

inert gas and free from oxidation. Oxidation along the tack weld edges can lead to a leak path in the weld.

- Always clean the surface prior to welding to remove any organic materials, moisture, and dirt. A dirty weld may result in chromium reacting to produce chromium carbide or may decompose during welding to create hydrogen gas and a porous weld.
- Always use aluminum oxide grinding wheels, not silicon carbide, for dressing of weld surfaces. The carbide may react with the chromium and decrease the corrosion resistance of the weld metal. Grinding wheels used on stainless steel should always be based on iron-free abrasives to avoid surface contamination by iron with associated possibilities of rust spots. If grinding wheels have been used on other ferrous metals, they should not be used on stainless steels (Ref 26).
- Because stainless steel has lower conductivity than carbon steel, 30% less heat input is required and the welds require longer cooling times.
- Since the coefficient of thermal expansion for austenitic stainless steel is higher than carbon steel or ferritic or martensitic stainless steels, low heat input should be used to prevent distortion and reduce residual stress.
- If multiple weld passes are required, maintain the interpass temperature at less than 100 °C (200 °F) to reduce the opportunity for cracking and distortion.
- Avoid crater cracks by controlling the size of the termination weld pool. If crater cracks occur, remove them by grinding the weld with an aluminum oxide wheel before proceeding.

The general rules for joining ferritic stainless steel equipment include:

- Low heat input should be used in the welding process to prevent excessive grain growth.
- Surface contamination with oil or other extraneous materials must be avoided to prevent the pickup of carbon during welding.
- To prevent nitrogen pickup during welding, the weld pool must be fully shielded with an inert gas. The actual gas used will depend on the welding process employed, but for the gas tungsten arc welding (GTAW) process, an argon or argon/helium mixture is recommended. Argon + 1 to 2% oxygen or argon/helium are the preferred gases for the gas metal arc welding (GMAW) process (Ref 24).
- In general, the maximum thickness of ferritic plates that can be welded is (3 mm) (0.125 in.) without structural integrity problems.

The general rules for joining duplex stainless steel equipment include:

- The weld procedure should be selected to produce a weld with good phase balance of ferrite and austenite. Rapid cooling rate would promote too much ferrite formation, which may lead to a ductility reduction, while slow

cooling rate can result in too much austenite formation. Too much austenite formation may reduce SCC resistance.

- Typically 100% argon is used as a shielding gas. However, for welding of thin sections to each other or thin sections to thick sections, 1 to 3% nitrogen should be added to promote austenite formation because of the faster cooling rates of thin sections.
- Autogenous welding (welding without filler metal) is not recommended because it may promote too much ferrite formation and reduce ductility and corrosion resistance. Gas tungsten arc welding is the recommended weld process. Filler metal (usually nickel overalloyed filler) is mandatory.
- Preheat and postweld heat treatment are not normally required or recommended. Preheat would slow the cooling rate, which may lead to too much austenite formation and reduce the resistance to SCC.
- As with ferritic stainless steels, heat input should be minimized through low-diameter welding wire/electrodes and low welding currents avoided (Ref 24).

Avoiding Corrosion Problems in Stainless Steels

Liquid Flow Rate and Stagnant or Dead Leg Areas. Stainless steels maintain their corrosion resistance due to the passive film formed on the surface. Pitting corrosion occurs due to the film breakdown at locations where locally concentrated pockets of chloride or other halide ions occur. Pitting corrosion occurs more readily under any dirt deposits such as "milkstone" (a deposit found in the dairy industry originating from milk and hard water consisting primarily of protein and calcium phosphate) or in stagnant areas. Stainless steel pitting risk can be significantly reduced by maintaining high fluid flow rates and/or eliminating stagnant areas. Higher flow rates not only scour the surface of deposits, but also provide more oxygen to the surface, which will result in the formation or reformation of a more stable passive film.

Avoid Crevices and Discontinuities. Crevices or discontinuities can trap fluids that harbor bacteria growth and encourage solids buildup on metal surfaces (Ref 26). Such crevices and discontinuities will increase the possibility of crevice corrosion and localized corrosion such as pitting.

Select Appropriate Surface Finish. Although surface finish is important for equipment cleanability, smooth surface finish also reduces the susceptibility to corrosion. Since stainless steel corrosion usually occurs as localized corrosion, a smoother surface that has less adherence of milkstone, "beerstone" (the deposition of hardness salts and proteinaceous matter in the brewing industry), and "winestone" has a reduced possibility of suffering localized corrosion. In general, a 150 grit finish (3A finish from

3A Dairy Standard (Ref 27) and No. 4 finish from AISI classification) is adequate for most food and brewery services. Table 3 lists various finishes classified by the AISI (American Iron and Steel Institute).

Hydraulic Pressure Testing (Hydro-testing). If possible, use deionized (DI) water for any hydraulic pressure test. If other water types are used, completely drain and dry the system immediately after the test to prevent pitting corrosion, which may otherwise occur in times as short as overnight.

Stainless Steel Corrosion Case Studies

Stress Corrosion Cracking of Type 304 Stainless Steel Vessel. In a U.K. sweets-manufacturing company, a 570 L (150 gal) type 304 stainless steel jacket vessel containing a glucose and citric acid mixture at 100 °C (212 °F) with chloride present had severe SCC after only 18 months of service. Cracking started on the product side and completely penetrated the vessel wall while there was no sign of general corrosion. Similar corrosion problems were also found in welded pipework handling the same type of food product. The solution to this SCC problem was installing alloy 825 (N08825), a nickel alloy containing 40% Ni, 20% Cr, 3% Mo, and 2% Cu (Ref 15).

Pitting of Type 304 Stainless Steel Plate and Frame Heat Exchanger. In a French beet sugar mill, severe pitting was found on the type 304 stainless steel plates in a plate-type heat exchanger. Pitting occurred after only 12 months of service. Failure analysis tests showed that deposits in the pits contained 500 ppm chloride. Type 316 stainless steel plates were evaluated and, although better than type 304, were still pitted to some extent (Ref 15). Titanium would provide a better solution for this application.

Stress-Corrosion Cracking of Type 304 Stainless Steel Conveyor-Belt Components. Conveyor belts used by a food company in preparing hot dogs were made of type 304 stainless steel. Hot dogs contain salt and are cured at 80 to 82 °C (175 to 180 °F). The presence of chloride and elevated temperature combined with the residual stress in the conveyor belt side links caused SCC failure in about 2 years. To solve this problem, all the conveyors were converted to type 444 ferritic stainless steel and have been functioning without SCC for more than 5 years (Ref 22).

Stress-Corrosion Cracking of Type 304 Pressure Cooker. A major manufacturer of restaurant pressure cookers for chicken experienced SCC failure of these units at the flanges due to the combined effect of high temperature and salt in the cooking oil. Conversion to type 444 ferritic stainless steel solved the problem (Ref 22).

Stress-Corrosion Cracking of Type 304 Stainless Steel Glucose Tank. A major brewery in Canada suffered SCC of a type

304 glucose tank. The temperature and the chlorides in the glucose provided the necessary ingredients for SCC. The problem was solved by substituting a type 444 ferritic stainless steel tank (Ref 22).

Other Materials of Construction

The materials described in this section offer alternative solutions to stainless steels, but often do not compete because of the wide-ranging beneficial properties of stainless steels.

Aluminum is still used extensively in certain areas of food manufacture and distribution because of its good corrosion resistance, cleaning ease, material of construction cost, material weight, and high thermal conductivity (Ref 28). Examples of aluminum applications include beer kegs, beer cans, soft drink cans, and numerous small-scale equipment uses in the brewing industry (Ref 28). In other food manufacturing and preparation areas, aluminum is used extensively to process butter, margarine, table oils, edible fats, meat and meat products, fish and shellfish, and certain sorts of vinegar, mustards, and spices (Ref 28). The primary factor limiting the widespread use of aluminum in the food and beverage industries is its susceptibility to galvanic corrosion due to its very negative open circuit potential. Aluminum also cannot survive the harsh cleaning chemicals and conditions required for clean-in-place applications, because the pH range over which it is resistant is relatively narrow.

Copper has been the traditional metal used in breweries for centuries due to its excellent thermal conductivity, ductility, fabricability, and reasonably good corrosion resistance. However, with the use of new alkaline cleaners, some corrosion problems have occurred. Conventional brazed joints in large-diameter kettles have been preferentially corroded and required silver braze repair. Metal toxicity and its catalytic activity in the development of oxidative rancidity in fats and oils have limited the use of copper as a material of construction in the food industry (Ref 28). Even at the sub-part-per-million level, copper in vegetable oils and animal fats rapidly causes the development of off-flavors (Ref 28).

Table 3 Surface finishes on stainless steel sheet

Finish	Surface description
No. 1	Hot-rolled, annealed, and descaled
No. 2B	Cold-rolled, annealed, and descaled plus light planishing pass between polished rolls (bright finish)
No. 2D	Cold-rolled, annealed, and descaled (dull finish)
No. 3	Polished finish (100 mesh grit)
No. 4	Polished finish (120–150 mesh grit), general-purpose finish for food equipment
No. 6	Dull satin polish finish
No. 7	Bright polish finish
No. 8	Mirror polish finish

Titanium. There are certain areas of the food industry, especially in equipment involving heat transfer, where stainless steels just cannot withstand the corrosive effects of salty, low-pH environments (Ref 28). Titanium is increasingly being accepted as an alternative in such cases. It is believed titanium is the only answer to address corrosion under the most aggressive conditions. For example, a well-known food processor has been using titanium for many years for processing hot salted cream cheese and salted dressings containing vinegar and salt. The titanium performed well and solved a pitting problem by replacing the stainless steels (Ref 29).

It was reported in 1981 that several hundreds of plate-type titanium heat exchangers were employed by the American food industry, and many of them had been in service for ten years. These heat exchangers were employed very successfully in corn products, barbecue sauce, pickles, salad dressings, and other foods with temperature ranging up to about 120 °C (250 °F) (Ref 29). One company found that titanium equipment lasted three times longer than stainless steel equipment in a hot bean sauce (Ref 29).

Titanium is a light metal with a high strength/weight ratio. Its density is almost half of stainless steels. Although relatively expensive, the low density of titanium can offset the price differential for the raw material by almost 50%.

Corrosion in Cleaning and Sanitizing Processes

An important activity in any food-processing system is the elimination of microbial growth or contamination since it directly affects food product safety, quality, and shelf life. Clean processing systems are usually characterized by frequently executed cleaning and sanitizing processes. In these processes, cleaning chemicals are used to remove various inorganic and organic soils, and sanitizing chemicals are used to disinfect the equipment or piping surface. Although stainless steels can survive most of the cleaning and sanitizing environments created by these corrosive chemicals, corrosion can still occur if the cleaning and sanitizing process parameters are not properly controlled. The critical parameters of the cleaning and sanitizing process include the chemical concentration, temperature, and duration of the cleaning and sanitizing process.

Sodium hypochlorite sanitizing compounds are normally supplied in alkaline solution with 3 to 15% available chlorine. These solutions function most efficiently in the pH range 8 to 9. Values higher than pH 9 result in slower germicidal action and lower corrosion rates, whereas values below pH 8 provide rapid germicidal action but excessive corrosion rates (Ref 15). To ensure the best sanitizing conditions while avoiding stainless steel pitting, process parameters such as the sodium hypochlorite concentration, temperature, and duration of contact time, should be controlled in the sanitizing

process. The recommended concentration of sodium hypochlorite in the sanitizing solution is 200 ppm. The contact time with stainless steel surfaces should not be more than 30 min. Solution temperature greater than 49 °C (120 °F) can increase the corrosive effect and eventually may cause pitting (Ref 30). The maximum recommended temperature for a 200 ppm sodium hypochlorite is 49 °C (120 °F) to prevent pitting.

Gluconic acid solutions are effective in removing beerstone deposits, and they do not corrode the stainless steel equipment. Stainless steel brewery fermenting tanks with aluminum fittings have been successfully cleaned with a 4 to 5% solution of gluconic acid (Ref 15, 31) at temperatures in the range of 15 to 35 °C (60 to 95 °F). The formulation shown in Table 4 has been found to be useful in removing beerstone from stainless steel beer barrels (Ref 15).

Phosphoric Acid. Milkstone deposits can be removed conveniently from milking machines and other equipment with 30% phosphoric acid solution containing 2 to 5% of a nonionic wetting agent, used at the rate of 6 to 30 g/L (1 to 5 oz/gal) of hot water at 70 to 80 °C (160 to 180 °F) (Ref 15, 32).

Prerinse of the milking system is accomplished using clean warm water (38 to 43 °C, or 100 to 110 °F) to remove residual fat, protein, and sugars. The rinse temperature should not exceed 46 °C (115 °F) since the soil can be "cooked" onto the equipment or piping surface and become harder to remove (Ref 30).

Milk and wash lines should be looped to avoid "dead ends" in the piping system (Ref 30). These dead ends not only create poor cleaning, but also generate an environment that facilitates corrosion due to chemical accumulation and/or oxygen depletion.

Mechanically Assisted Cleaning and Clean-in-Place (CIP). Effective cleaning requires both chemical and mechanical action. In a manual operation, the mechanical action should come from the use of the appropriate brushes and physical effort. Metal scouring pads, wire bristle brushes, or other abrasive materials should be avoided, as these cleaning tools can damage the surface being cleaned (Ref 30). For CIP systems, mechanical action is achieved from the solution turbulence, which is a result of the fluid velocity. The minimal acceptable fluid velocity flow for the CIP solutions through the system should be 1.5 m/s (5 ft/s) (Ref 30), but a higher velocity of 2 m/s (7 ft/s) is more desirable.

Table 4 Solution for removing beerstone from stainless steel barrels

Chemical	Quantity
Caustic soda, kg (lb)	9–11 (20–25)
Sodium gluconate, kg (lb)	4.5–9 (10–20)
Sodium oleate, kg (lb)	0.045–0.09 (0.1–0.2)
Water, L (gal)	45 (12)

Material Issues in the Pharmaceutical Industry

Paul K. Whitcraft, Rolled Alloys

THE OVERVIEW of materials of construction corrosion failure mechanisms in the article "Corrosion in the Pharmaceutical Industry" in this Volume continues to be a valuable resource for information on this topic. Some trends in the availability and application of materials in this industry, and current issues relative to pharmaceutical equipment construction, warrant closer examination.

Materials

In an industry conservative by nature, the change in material use is slow to occur and driven primarily by the failure of existing material systems to resist corrosion from new processes. Equipment involved in product contact has been constructed largely from austenitic stainless steel 304L (UNS S30403) and 316L (UNS S31603). The satisfactory performance of these materials in most applications, combined with good material availability at acceptable price levels, produces little incentive to change. Historically, in areas where 316L was not adequate, the high-Ni-Cr-Mo alloy C-276 (UNS N10276) was the alternate choice.

In the 1970s and 1980s, numerous alloys intermediate to 316L and C-276 were developed that offered the chemical and corrosion resistance necessary for the pharmaceutical industry. A few of these alloys are popular in the sense of market availability and use, and while alloy development continues, it is at a much slower pace. These alloys can generally be characterized into two families, identified as super-austenitic and duplex stainless steels.

Superaustenitic Stainless. Of the super-austenitic stainless alloys, the AL-6XN (Allegheny Ludlum) alloy (UNS N08367) has been the most widely used. This alloy is nominally 25Ni-20Cr-6Mo, with the balance essentially iron. See the article "Corrosion of Nickel and Nickel-Base Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005, for information on other Ni-Cr-Mo alloys and aqueous and high-temperature corrosion. The high-chromium and molybdenum additions

result in an alloy that is very resistant to pitting attack, but more importantly, resistant to crevice corrosion. Laboratory tests for evaluating resistance to localized corrosion have been developed and are useful in determining the relative resistance of various materials to acid chloride environments. These tests should not be used to predict precise behavior in other environments, and comparison of one data set to another must be done with caution because there can be variability in results. However, materials showing resistance in these tests have demonstrated an ability to perform well under conditions where 316L has failed due to localized corrosion, such as crevice corrosion.

Crevice corrosion occurs in 304L and 316L stainless steels when the conditions in a tight crevice become more severe than the surrounding environment. Stainless steels gain their corrosion resistance by forming a protective oxide surface layer. This layer, composed primarily of chromium oxides, is readily formed in the presence of oxygen. This protective layer is susceptible to damage from halogens, but if oxygen is present in the environment, repair of the film is often rapid enough to prevent any significant damage. In the absence of a source to replenish oxygen, such as in a tight crevice, corrosion can accelerate as the available oxygen is consumed and the pH drops as a result of the corrosion process.

Another location where depleted oxygen can lead to corrosion of stainless steel is at low points of piping systems without adequate drains.

Duplex Stainless Steels. A number of duplex stainless steels exist. Alloy 2205 (UNS S32205) contains 22Cr-5Ni-3Mo and is widely used in industrial and chemical process applications. To date, duplex alloys have seen little application in pharmaceutical equipment, but their relative cost and properties make them suitable candidates to replace 304L and 316L. The chromium and molybdenum contents result in a material with pitting and crevice corrosion resistance superior to that of 316L stainless and that is also resistant to chloride-induced stress-corrosion cracking because of the austenite-ferrite (duplex) microstructure. In general, duplex alloys are magnetic, slightly less formable, and require more care in fabrication than the austenitic grades.

The correlation between resistance to chloride pitting and crevice corrosion and alloy content is shown in Table 1. Nitrogen has become an important alloy addition in these alloys as well. A pitting index, called the pitting resistance equivalent number (PREN) with nitrogen, has been developed to predict resistance of an alloy based on its composition. The PREN is defined as $\%Cr + 3.3 \times \%Mo + 30 \times \%N$. Other PREN formulas use $\%Cr + 3.3 \times \%Mo + 16 \times \%N$, so it is important to know the basis of the value when making comparisons. There is a term for tungsten in other PREN formulas. The level of localized corrosion resistance offered by the duplex and superaustenitic stainless steel materials fills the large gap between 316L and C-276. The superaustenitic stainless grade should be

Table 1 Typical corrosion characteristic values for materials of construction in the pharmaceutical industry

Alloy	UNS No.	Pitting resistance equivalent number (PREN)(a)	Critical pitting temperature(b), °C	Critical crevice temperature(c), °C	Stress-corrosion cracking, boiling 25% NaCl
304L	S30403	19.8	0(d)	<−3	Cracks in <72 h
316L	S31603	24.9	15	−3	Cracks in <72 h
2205	S32205	37.6	40	17	Resists
AL-6XN	N08367	47.2	80	43	Resists
C-276	N10276	65.0	>110	>75	Resists

(a) Using $PREN = \%Cr + 3.3 \times \%Mo + 30 \times \%N$. (b) ASTM standard G 48, method C, critical pitting temperature test. (c) ASTM standard G 48, method D, critical crevice temperature test. (d) Estimated

seriously considered as a less expensive alternative to the higher-nickel alloy. Also see the articles "Corrosion Resistance of Stainless Steels and Nickel Alloys" and "Effects of Metallurgical Variables on the Corrosion of Stainless Steels" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Material Replacement. With advances in melting technology, primarily the argon-oxygen decarburization refining process that facilitated the development of these higher alloys, came the ability to control alloy content to more precise levels. One result of this advancement to the end user is that the alloy content of grades such as 316L is actually lower than it was 25 years ago. Given the ability to control molybdenum levels to tighter ranges, it is not surprising that the molybdenum content in 316L today (2006) is typically below 2.1%, while 25 years ago it probably averaged nearer 2.5%. This has resulted in a significant cost-savings to users of these alloys in most applications. In those areas where the alloy offered corrosion resistance that was barely adequate, the subtle change in chemistry may mean that a replacement 316L component no longer performs well in areas where it was once satisfactory.

Passivation

Stainless steels offer useful corrosion resistance because they exhibit passive corrosion behavior as a result of the formation of protective oxide films on the exposed surfaces. Under normal circumstances, stainless steels will readily form this protective layer immediately on exposure to oxygen. This oxygen may be from any source, including air, dissolved oxygen in water, or other oxidizing media. When this protective film is violated or fails to form, active corrosion is likely to occur. Some fabrication processes can impede the reformation of the passive layer, and, to ensure that it is formed, stainless steels are subjected to passivation treatment. The common concern in this regard is contamination of the surface by carbon steel. This local contamination may result from a variety of causes, including handling equipment, forming tools, fixtures, and clamps.

Treatments. The production of stainless steels commonly involves the use of strong oxidizing acids such as nitric and nitric-hydrofluoric acid mixtures to remove the oxide scales formed during thermal treatment. This pickling process provides two benefits. First, it removes the oxide scale and passivates the underlying metal surface. Second, due to its aggressive nature, the process will remove any chromium-depleted layer that may have formed as a result of the scale formation.

For passivation treatments other than scale removal following thermal treatment, less aggressive acid solutions are usually employed. The primary purpose of these treatments is to remove contaminants that may be on the component surface and could prevent the formation

of the oxide layer locally. The most common contaminant is embedded or free iron particles from forming or machining tools. Mechanical polishing can be employed to provide a uniform surface finish and remove these contaminants. The polishing materials used should be devoted to stainless steel use only, because they can carry over small particles from one part to the next. In addition, these fine work-hardened particles, even from a stainless vessel, can have a lower threshold for corrosion and act as an initiation site if not removed. A dilute (10%) solution of nitric acid is effective at removing free iron or similar contaminants. For ferritic, martensitic, or precipitation-hardening grades, a nitric acid solution inhibited with sodium dichromate is used so as not to attack the stainless too aggressively. Phosphoric acid at 1% concentration and citric acid at up to 20% concentration are also effective for the more resistant stainless alloys. Other commercially available chelating agents can be employed. The use of these mild acids or chelating agents can also represent a significant advantage in terms of relief from environmental issues.

Welding. A passivation treatment is also advisable following welding. Welding processes, even with proper gas shielding, may result in some oxidation (heat tint) on or adjacent to the weld. Under severe corrosion conditions, these areas will be more likely to initiate corrosion. However, the magnitude of the increased tendency to corrode is difficult to quantify, and in many instances, this condition may have no impact on actual service performance. Only extensive corrosion testing or trial experience should be used to justify the serviceability of material exhibiting heat tint. Cleanup of localized areas is best addressed through conventional weld-cleaning methods, such as pickling pastes. Electrolytic pickling and descaling processes may also be effective. Stainless wire brushing is also an acceptable means of heat tint removal. The conventional postfabrication passivation techniques, such as dilute phosphoric, nitric, or citric acid, will not remove the heat tint from welding. However, such treatments will ensure that no free iron or active areas remain.

Further information on pickling, passivation, and cleaning treatments may be found in ASTM International standards A 380 (Ref 1) and A 967 (Ref 2).

Electropolishing

Electropolishing is a controlled corrosion process, resulting in the uniform removal of metal from the surface. See the article "Electropolishing" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. Electropolishing is not a passivation treatment, although the proper execution of the process will result in a passive surface. Proper electropolishing technique maintains the part in the electrochemically

passive range, while the passivated layer is only allowed to grow several atoms thick, at most. The electrolyte simultaneously promotes dissolution of this layer. The electropolishing process does remove surface impurities, as is accomplished with passivation. During the cleaning and rinsing process following electropolishing, the material does passivate naturally upon exposure to oxygen-containing rinse water or air. Ultimate passivation of the surface is assured, because any contaminants that may have been on the surface have also been removed by the polishing process. No additional passivation procedure is required. In fact, exposure to some passivation treatments, such as dilute nitric acid, may be detrimental to the intended result by dulling the luster of the polish.

Electrolytes used for electropolishing are usually proprietary mixtures with contents that are not quantitatively revealed. The electrolyte will typically have the ingredients to facilitate three different actions of the polishing process:

- An etchant that facilitates the breakdown of a passive film
- An oxidizer that helps form a passivating film
- A highly viscous constituent that promotes the formation of a diffusion layer

The oxidizer and the etchant assist in maintaining the part in a pseudopassive state, while the diffusion layer control is necessary to promote uniform metal loss. For electropolishing 316L stainless, the electrolyte will often contain perchloric acid, which can provide both oxidizing power and a halide etchant. Acetic anhydride may be used to control the diffusion layer. Stainless and higher-nickel alloys may also use nitric acid, sulfuric acid, phosphoric acid, hydrogen peroxide, and methyl alcohol. Determining the ideal electrolyte ingredients is an important part of the polishing process. Because electropolishing is an electrochemical process, other variables to be controlled include the voltage, current density, and solution temperature. Voltages that are too low can cause etching of the surface due to more rapid general corrosion. Voltages that are too high will result in pitting. Part geometry and cathode design are critical, because it is imperative that the current be distributed as uniformly as possible over the part surface. High current densities will also result in pitting.

The large majority of stainless steel production today (2006) is by the argon-oxygen decarburization (AOD) process, followed by continuous casting. The AOD process, along with other controls in the steel-making process, has resulted in a more consistent and uniform product. Continuous casting does create the opportunity for types of surface or near-surface imperfections that can have an impact on electropolishing behavior. Static casting of ingots can result in similar problems with cleanliness. Although electropolishing imperfections on AOD stainless products are rare, the use of a double-melted product will ensure an essentially imperfection-free electropolished

surface. The benefits of making this a requirement, however, must be weighed against increased cost and decreased availability.

Rouging

Rouging is a phenomenon of particular interest to the pharmaceutical industry. It is the presence of a surface layer of oxide on stainless equipment or piping typically handling high-purity water at temperatures above ambient. This includes stills, steam systems, purified water, and water for injection. The oxides can vary in composition, degree of oxidation, color, texture, and adherence. Although generally shown to be innocuous, the mere presence of these deposits can raise concern.

The rouge itself is typically composed primarily of iron oxides or iron hydroxides, but because these are developing on stainless surfaces, they may also contain oxides of chromium, nickel, and molybdenum. There is empirical data indicating that resistance to rouging increases with increasing chromium-iron ratios in the passive layer and/or the thickness of the passive layer itself. Because both electropolishing and passivation increase the chromium-iron ratio, application of these processes can increase resistance to rouging. Even with such treatments, the passive layer can break down due to the ionizing effect of high-purity water. The low oxygen content of these waters also slows the rate of repassivation and may cause the layer to linger in intermediate states of oxidation. Repeated cycles of this process result in the entrapment of various oxides in the passive layer, hence the wide range of colors.

Rouging has also been observed to result from deposits of corrosion products from upstream equipment. Such deposits can simply be wiped from the surface and reveal an unaffected electropolished surface underneath. Upstream equipment potentially identified as the source has included stills (often with carbon steel components), lower-alloy stainless steel piping

(304L/316L) welds, and stainless pump components. Stainless pump housings are often produced from as-cast products. Foundry castings often contain higher ferrite contents than wrought stainless steels to facilitate castability. Ferrite contents in cast 304 or 316 products (CF-8, CF-8M) can exceed 20%, and these may be less corrosion resistant than their wrought counterparts that typically contain no more than 5% ferrite.

Removal of rouging can be accomplished mechanically but is usually addressed by chemical cleaning. Repassivation treatments with nitric, phosphoric, citric, or other oxidizing acid solutions have been effective in removing or fully reoxidizing this layer. As with any chemical reaction, the process is time-dependent and can be influenced by temperature. For more resistant rouge patterns, reducing acids such as hydrofluoric or hydrochloric may be used in combination with a passivation treatment. The use of these acids in strong concentrations, however, may etch the surface.

Potentiodynamic polarization studies have been conducted to measure the efficacy of passivation treatments. It has been shown that the breakdown (pitting) potential is raised by passivation or electropolishing techniques that result in higher chromium-iron ratios and increased thickness of the passive layer. These potentials can be increased by as much as 50 to 100 mV over mechanically polished or pickled surfaces and have been equated to increased resistance to rouging. Additionally, the breakdown potential of the molybdenum-bearing superaustenitic stainless alloy N08367 was shown to be in excess of 400 mV higher than 316L prior to enhancing passivation treatments, and another 50 mV higher following such treatments. Such studies would suggest that higher alloys, such as N08367 or the C-276-type alloy, are highly resistant to rouging.

Issues of rouging have recently attracted the attention of at least two organizations concerned with materials performance. ASTM International Committee G-1 on corrosion is

considering the development of a test method that could be used to evaluate a material resistance to rouging. The existence of such a test method could help in understanding the conditions under which rouging will occur, as well as provide an indication of the materials that will resist its formation. The Materials Technology Institute of the Chemical Process Industries is developing a project designed to better define the sources and mechanism of the formation of rouge, and this program anticipates funding work to identify the mechanism and ways to prevent its formation. See the article "Rouging of Stainless Steels in High-Purity Waters" in this Volume for details on the water chemistry, materials of construction, and classification of rouge.

Corrosion in the Pharmaceutical Industry

THE PREVENTION AND MITIGATION of corrosion in the pharmaceutical industry presents a demanding challenge to materials engineers. In most cases, the processes require equipment and piping systems to be fabricated from material having extremely low corrosion rates when exposed to a wide variety of corrosive media and operating conditions. Any substance produced by corrosion reactions could contaminate the product being manufactured. This contamination must be removed in a subsequent process step so that the product is in compliance with the stringent purity and quality demands established by the applicable government regulatory agencies for the good of the consumer.

Materials of Construction

The materials of construction found in pharmaceutical production facilities include:

- Metal alloys, both solid and clad
- Thermosetting plastics and thermoplastics, both solid and as linings
- Ceramics and glass, both solid and as linings
- Impregnated carbon

Stainless Steels

The articles "Corrosion of Wrought Stainless Steels" and "Corrosion of Cast Stainless Steels" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005, provide details on the general use of stainless steels. The article "Material Issues in the Pharmaceutical Industry" in this Volume provides further information.

Austenitic stainless steels, especially low-carbon and stabilized grades, have been the dominant alloys in the pharmaceutical industry. These alloys exhibit good corrosion resistance in many media, are easily fabricated, have excellent strength over a wide temperature range, are readily available, and are relatively inexpensive. The surface condition of the austenitic stainless steel is critical where it is in contact with the pharmaceutical product and where the stainless steel is required to resist an aggressive environment. The highly protective chromium oxide film that gives stainless steel its corrosion resistance is tenacious, durable, and self-healing in the presence of oxygen; however, this film can be damaged during fabrication and by cleanup practices after fabrication. Fortunately, problems

can be minimized by following good design, procurement, fabrication, handling, and cleanup practices.

Austenitic stainless steels are widely used in oxidizing environments, high-purity water service, and in fine chemical and pharmaceutical production equipment and piping. They are not suitable for use in chloride-containing environments, particularly at high chloride concentrations and at high temperatures.

Stainless steel producers have developed more highly alloyed superaustenitic stainless steels having excellent resistance to general corrosion, pitting, and crevice attack in chloride-containing environments. These alloys are highly resistant to intergranular corrosion and stress-corrosion cracking (SCC); this makes them useful in oxidizing chloride solutions, oxidizing acids, and brines. The high molybdenum (2.5 to 6.5%) content and increased chromium and nitrogen give the superaustenitics good resistance to pitting and crevice corrosion. The relatively high nickel content (18 to 31%) and the high chromium and molybdenum levels give the alloys excellent SCC resistance. The presence of copper in the alloys improves resistance to sulfuric (H_2SO_4), phosphoric (H_3PO_4), and acetic acids.

The superstainless alloys are less costly than the nickel-base alloys and are readily available in a wide range of product forms, such as pipe and tubing, sheet, plate, and forgings, as well as a full range of welding consumables. In addition, the superaustenitic stainless steels are more workable and have better weldability than high-alloy ferritic steels. When the superaustenitics are specified, the welding specifications of alloy producers should be followed explicitly so that the full chemical and cracking resistance of the alloy is maintained.

Duplex stainless steels are duplex in structure; at room temperature, their equilibrium structure is a mixture of austenite and ferrite phases. The compositions of these alloys are carefully controlled to maintain the proper balance of austenite to ferrite. Most of the physical properties of the duplex stainless steels are between those of the austenitic and ferritic stainless alloys. The thermal conductivity of the duplex stainless alloys is less than half that of carbon steel but approximately 25% higher than that of the austenitic stainless steels.

The coefficient of thermal expansion of carbon steel is similar to that of the stainless

duplex alloys and is approximately 40% less than that of the austenitic stainless alloys. Duplexes have excellent toughness as well as high strength. Compared with the ferritic stainless steels, the ductile-to-brittle transition of the duplex alloys is more gradual and occurs at a lower temperature, thus allowing the production of a wide range of product forms.

The duplex alloys are not suitable for cryogenic service; the austenitic grades are preferred in this application. The duplex grades have good resistance of chloride SCC; however, the various alloys can show variability in pitting and crevice-corrosion susceptibility because of the segregation of the ferrite and austenite phases. The high chromium content of the duplex stainless steels makes them strongly resistant to oxidation. However, prolonged exposure at elevated temperatures (above 345 to 370 °C, or 650 to 700 °F) can affect toughness and corrosion resistance in aqueous media.

All commonly used duplex stainless steels are included in ASTM International specifications for sheet, strip, plate, and seamless and welded tubing and pipe. Many duplex stainless steels are also included in Section VIII, Division 1, of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code. These steels are called austenitic/ferritic corrosion-resistant steels in international standards such as EN 10213-4.

The best corrosion resistance and mechanical properties in welded duplex stainless steels are achieved when a 50-50 austenite-ferrite phase is formed in both the weld metal and the heat-affected zone (HAZ). Welding practices that emphasize cleanliness, avoid carbon contamination, and use dry inert gas shielding are required. Because of the sensitivity of ferrite to hydrogen embrittlement, shielding gases containing hydrogen should not be used. Duplex alloys include alloy 2205 (UNS S31803), 44LN (UNS S31200), and Ferralium 255 (UNS S32550).

High-purity ferritic stainless steels were introduced in the United States in the 1970s. The oldest, E-Brite 26-1 (26Cr-1Mo, UNS S44627), was first electron beam refined for low carbon and gas content and is now vacuum melted. Other high-purity ferritic alloys with similar chromium and molybdenum contents and stabilizing additions of titanium have been introduced. The 26-1 alloy generally has corrosion resistance equal to or better than types 304 and

316 stainless steel. In addition, the 26-1 alloy is resistant to chloride-induced SCC, a major shortcoming of the austenitic stainless steels. With the introduction of argon oxygen decarburization, a variety of new alloys were possible.

Welded ferritic stainless steels typically have poor weld zone ductility and are notch sensitive in the HAZ. If these alloys are heated to between 400 and 480 °C (750 and 900 °F) for prolonged times or are slowly cooled within this temperature range, notch toughness is further reduced, and the material becomes brittle. The use of the ferritics at low temperatures is limited because of their high ductile-to-brittle transition temperatures. If the corrosion resistance of the ferritic alloys is to be maintained, extreme care must be taken to avoid contamination with nitrogen, oxygen, hydrogen, or carbon during welding. Detailed tungsten inert gas welding procedures developed by the alloy producer should be used to maintain ductility and corrosion resistance.

Nickel and Nickel-Base Alloys

See the article "Corrosion of Nickel and Nickel-Base Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005, for additional details.

Commercially pure nickel, nickel 200 (UNS N02200), is highly resistant to many corrosive media. It is most useful in reducing environments, and it can be used under oxidizing conditions that cause the development of a passive oxide film. Nickel has poor corrosion resistance in H_2SO_4 , HCl , HNO_3 , and H_3PO_4 . Pure nickel has outstanding resistance to alkalis, the exception being ammonium hydroxide (NH_4OH), which rapidly corrodes nickel. Oxidizing acid chlorides such as ferric, cupric, and mercuric are very corrosive. Nickel is used for containing very reactive chlorides, such as phosphorus oxychloride, phosphorus trichloride, nitrosyl chloride, benzyl chloride, and benzoyl chloride. Pure nickel resists anhydrous chlorine, anhydrous hydrogen chloride, phenol, and bromine.

Nickel-Copper Alloys. Alloy 400 (UNS N04400) is more resistant than nickel to corrosion under reducing conditions and more resistant than copper to corrosion under oxidizing conditions. As a solid-solution alloy 400 is free from the corrosion that can result from local galvanic action between the phases of multiphase alloys. Alloy N04400 is generally resistant to SCC; exceptions are mercury and solutions of its salts, fluorosilicates, concentrated caustic soda (NaOH), and potassium hydroxide (KOH). Alloy N04400 is resistant to all common dry gases at room temperatures. It is not resistant to chlorine, bromine, nitric oxides, ammonia, sulfur dioxide, and hydrogen sulfide in the presence of moisture. It is useful in handling H_2SO_4 under air-free reducing conditions. Aeration causes a sharp increase in the corrosion rate. Alloy N04400 can handle aerated HCl at 10% concentration at room temperature; above room

temperature, applications are usually limited to 3 to 4% HCl . In unaerated hydrofluoric acid (HF), N04400 is resistant to all concentrations up to the boiling point. It has very poor corrosion resistance in HNO_3 but has good resistance to NaOH up to approximately 50% concentration and to NH_4OH up to 3% concentration.

Nickel-Chromium Alloys. The high nickel content of these, such as alloy 625 (UNS N06625), gives them considerable resistance to corrosion under reducing conditions and in strong alkaline environments. Also, because of the high nickel content, the alloys are virtually immune to chloride SCC. However, at high temperature and in contact with concentrated alkalis, they are subject to SCC. Mercury will also cause SCC at elevated temperatures.

Nickel-molybdenum alloys were developed to be resistant to HCl at all temperatures and concentrations. The nickel-molybdenum alloys have good corrosion resistance to other non-oxidizing environments, including boiling 60% H_2SO_4 , pure H_3PO_4 at most concentrations and temperatures, wet hydrogen chloride gas, hydrogen chloride to 455 °C (850 °F), and wet halogenated organics. The presence of ferric or cupric salts or other oxidizing agents will cause rapid corrosion of these alloys.

Nickel-Chromium-Molybdenum Alloys.

The addition of chromium to the nickel-molybdenum alloys increases the resistance to oxidizing environments, giving them good resistance to HNO_3 and H_3PO_4 , as well as to most chloride salts. The alloys are very resistant to pitting and crevice corrosion because of the molybdenum content. The nickel-chromium-molybdenum alloys are the most versatile corrosion-resistant alloys available. They are some of the few alloys that are resistant to wet chlorine gas, hypochlorite, and chlorine dioxide solutions. They have good resistance to ferric and cupric chlorides and other oxidizing salts, alkalis, and acids.

Nickel-chromium-molybdenum-copper alloys were developed to resist H_2SO_4 and HNO_3 over a wide range of concentrations and temperatures. They are resistant to H_3PO_4 , even when the acid contains fluorides or oxidizing compounds.

Titanium

Titanium forms a tight, adherent oxide film that makes it resistant to many oxidizing reagents, including HNO_3 and chromic acid (H_2CrO_4). Titanium is attacked by reducing acids such as H_2SO_4 and H_3PO_4 . It is useful in moist chlorine gas and hypochlorite at ambient and elevated temperatures; most organic acids; and water, seawater, and brine solutions at temperatures to the boiling point. At elevated temperatures, titanium is subject to pitting and crevice corrosion in a chloride environment. Titanium will not resist red fuming HNO_3 or HF in any concentration or temperature and will ignite at very low temperatures in dry chlorine

gas. More information on the corrosion of titanium and its alloys is available in the article "Corrosion of Titanium and Titanium Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Zirconium

The two zirconium-base alloys used most frequently in the pharmaceutical and chemical-processing industries contain some hafnium, which is metallurgically and chemically similar to zirconium and does not reduce its corrosion resistance. The alloy UNS R60702 contains a minimum of 99.2% (Zr + Hf), with a maximum hafnium content of 4.5%. The second alloy, UNS R60705, contains a minimum of (95.5% Zr + Hf), with a maximum of 4.5% Hf and 2.0 to 3.0% Nb. Both are approved for use in the construction of pressure vessels according to the ASME Boiler and Pressure Vessel Code, Section VIII. The hafnium content is limited for the nuclear grades of zirconium.

Zirconium has excellent resistance to HCl at all concentrations up to temperatures of 120 °C (250 °F). It resists HNO_3 in all concentrations up to 90% and temperatures to 150 °C (300 °F); however, SCC may occur above 70% concentration if high tensile stresses are present. Zirconium is corrosion resistant in H_3PO_4 in concentrations up to 55% at temperatures of 175 °C (350 °F). Above 55% concentration, the corrosion rate increases with temperature, but even in 85% H_3PO_4 at 60 °C (140 °F), the corrosion rate is still less than 0.13 mm/yr (5 mils/yr). If there are fluoride ion impurities present at any concentration of H_3PO_4 , zirconium may be subject to rapid corrosion attack. Zirconium alloys are resistant to H_2SO_4 up to 75% concentration and at temperatures to boiling. Ferric, cupric, and nitrate ion impurities cause corrosion of zirconium in H_2SO_4 concentrations above 65%. Fluoride ion concentrations as low as 1 ppm in 50% H_2SO_4 will cause corrosion of zirconium alloys. Zirconium has no corrosion resistance to HF and is rapidly attacked at concentrations as low as 0.001%.

Zirconium is resistant to virtually all alkaline solutions, either fused or in solution to boiling temperature. Zirconium has excellent resistance to corrosion in most organics and organic acids. It should be noted that SCC of zirconium occurs in ferric and cupric chloride solutions, concentrated HNO_3 , methanol-hydrochloric acid and methanol-iodine solutions, and liquid mercury or cesium. Detailed information on the corrosion of zirconium and its alloys is available in the article "Corrosion of Zirconium and Zirconium Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Impervious Graphite

Impervious graphite is made of raw graphite impregnated under pressure with phenolic,

furan, or fluorocarbon resins. The resulting nonporous graphite is impermeable to gases and liquids and is highly corrosion resistant in acids and many solvents. Impervious graphite is dimensionally stable, does not fatigue, and will withstand thermal shock. The phenolic and furan impregnants leach out from the graphite when exposed to ammoniacal compounds, NaOH and KOH, wet halogens, hydrogen peroxide (H_2O_2), strong HNO_3 , hypochlorites, and some solvents.

The introduction of the fluorocarbon impregnants to graphite has markedly increased corrosion resistance in solvents, acids, and alkalis. The maximum service temperature for the phenolic and furan impregnants is 170 °C (340 °F); for the synthetic fluorine-containing resin impregnant, 205 °C (400 °F).

Fluoropolymers

All fluorocarbons have high molecular weights, high melting points, and excellent chemical resistance. They have found wide application in chemical and pharmaceutical plants as pipe liners, nozzle liners, gaskets, expansion joints, valve liners, diaphragms for valves and pumps, seals and seal components, and barrier linings for vessels.

Polytetrafluoroethylene (PTFE) has a service temperature of 245 to 260 °C (475 to 500 °F) and is immune to most corrosive environments. Among the materials that attack PTFE are molten alkali metals and free fluorine. This material is rapidly permeated by bromine and oxides of nitrogen, and low-molecular-weight amines tend to plasticize the polymer. It can also be used at cryogenic temperatures, giving it the widest temperature range of any polymer.

Perfluoroalkoxytetrafluoroethylene (PFA) is a copolymer of tetrafluoroethylene and a perfluorovinyl ether. It has high molecular weight, making it suitable for extrusion and molding of parts. Ultrahigh-purity PFA has been developed for the pharmaceutical and semiconductor industries, where chemical inertness and freedom from contamination are needed. This complies with Food and Drug Administration (FDA) regulations as a coating that can be used in contact with food. The upper service temperature is 260 °C (500 °F), higher than fluorinated ethylene propylene. It is non-flammable and has high dielectric properties, low permeability, which is always helpful for lining and barrier applications, and possesses high tensile properties at elevated temperatures.

Fluorinated ethylene propylene (FEP) is a copolymer of tetrafluoroethylene and hexafluoropropylene. It is a fully fluorinated thermoplastic with a service temperature of 175 °C (350 °F). Like PTFE and PFA, this material is chemically inert, with a slightly lower permeability than that of PTFE. The uses for FEP are similar to those for PFA and PTFE.

Ethylene-chlorotrifluoroethylene (ECTFE) is the result of a 1:1 alternating copolymer of

ethylene and chlorotrifluoroethylene, having a service temperature of 160 °C (320 °F). Because ECTFE is not completely fluorinated, there are sites along the polymer chain at which chemical attack may occur. This material is attacked by aromatic solvents above 120 °C (250 °F), chlorinated hydrocarbons, ethers, methanol, butanol, and ketones above 65 °C (150 °F), acetic acid above 95 °C (200 °F), and H_2SO_4 and aromatic amines above 65 °C (150 °F). It resists mineral acids up to 120 °C (250 °F), inorganic alkalis, inorganic salts, and oxidizing acids at room temperatures.

Polyvinylidene fluoride (PVDF) is a crystalline, high-molecular-weight, partially fluorinated polymer of vinylidenedifluoride, having a service temperature of 135 °C (275 °F). It is attacked by hot alkalis, hot H_2SO_4 , solvents, and warm organic acids. This material has good resistance to chlorine, bromine, and their compounds; however, it will exhibit cracking when subjected to stress in the presence of nascent halogens. Virgin unplasticized PVDF has been successfully used for high-purity water piping as a replacement for electropolished type 316L stainless steel.

Glass-Lined Steel

This material offers the corrosion resistance of glass combined with the strength of steel, making it useful for process equipment operating at elevated pressure and temperature. Glass-lined steel has excellent resistance to corrosion over a wide range of pH and environments. Most glass-lined steel applications will not adversely affect product purity, flavor, or color. Glass-lined steel has an extremely smooth surface that resists fouling and is easily cleaned, which makes it attractive for use in pharmaceutical and fine chemical manufacture.

Corrosion Failures

The types of failures experienced in the pharmaceutical industry are similar in many ways to those seen in the chemical-processing industries (see the articles in the Section "Corrosion in the Chemical Processing Industry" in this Volume). Three primary causes of failure in the manufacture of pharmaceuticals—embedded iron, failures of glass linings, and corrosion under thermal insulation—are discussed.

Embedded Iron

A common problem during the fabrication of stainless steel equipment is the embedding of iron in the stainless steel surface. The iron corrodes when exposed to moist air or when wetted, leaving rust streaks. Larger embedded iron particles can also initiate crevice-corrosion attack in the stainless steel. Embedded iron cannot be tolerated in a fabrication destined for an application in the pharmaceutical industry

in which the stainless steel is used to prevent contamination.

Fabrication Practices. The following practices are recommended for minimizing embedded iron in fabrication. First, sheet, strip, and pipe are usually purchased in a surface finish called 2B (a bright, cold-rolled finish; see the article "Surface Engineering of Stainless Steels" in *Surface Engineering*, Volume 5 of *ASM Handbook*, 1994). Plate is normally hot rolled, annealed, and pickled and is furnished with a 2B mill finish. If a plate having a better surface finish is required, it should be specified during the procurement stage. When cleanliness is very important, sheet and plate can be ordered with a protective adhesive paper that can be left in place during storage and fabrication. Pipe and tubing can be ordered with protective end covers, especially if the pipe and tubing is to be stored outdoors.

Sheet and plates should be stored indoors and upright in racks, not horizontally on the floor. The dragging of sheets and plates over each other and worker foot traffic are often primary causes of embedded iron and deep surface scratches.

Care should be exercised in handling the sheet and plate on layout tables, forming roll aprons, and benches. This will minimize iron contamination.

Design plays an important role in iron contamination. Equipment and piping should be free draining. If internal attachments are needed, they should not interfere with free drainage. Bottom connections should be completely free draining. Vessel bottoms used as a work area during construction collect debris, and the foot traffic grinds the debris into the surface. It is suggested that the vessel bottom be flushed down and drained completely at the end of the workday to remove collected dirt and debris. If the vessel is a large flat-bottomed unit, a slatted wood floor should be installed to reduce the grinding of contaminants into the vessel bottom by foot traffic.

Testing new fabrications for embedded iron is relatively easy. The surfaces should be washed with clean water, drained completely, and after a 24 h waiting period, inspected for rust streaks on the surface. Water testing of the fabrication as a minimum should definitely be part of the equipment purchase order. For items to be used in a pharmaceutical plant, a precision inspection—the ferroxyl test for free iron (Ref 1)—should be specified in purchase documentation. This test can be easily performed in the field as well as in the fabricator shop.

Removal of Embedded Iron. Pickling is the most effective method of removing embedded iron. The surfaces must be cleaned of all surface oil, grease, and other organic materials so that the surface is wetted by the pickling solution. The pickling solution is a mixture of HNO_3 and HF at 50 °C (120 °F). The solution removes the embedded iron and other metallic contaminants and leaves the surface clean and in its most corrosion-resistant condition. It should be noted that HNO_3 alone will remove only superficial

iron contamination and will leave the deeply embedded particles. Small items are usually pickled by immersion. Piping and vessels that are too large for immersion can be pickled by circulating the pickling solution through them. It is recommended that a competent chemical cleaning contractor be employed for the pickling operation. If the ferroxy test shows only spotty patches of iron contamination, then it is recommended that these be removed by the use of an HNO_3 -HF pickling paste, rather than a complete pickling bath.

Another method of cleaning the stainless steel surfaces is the use of glass bead blasting. The beads should be clean and of a proper size to abrade the surface slightly and remove the contamination. Gritblasting and sandblasting are not recommended; they leave a rough profile that makes the stainless steel prone to crevice corrosion.

Organic contamination on stainless steel surfaces increases crevice corrosion. Contaminants include grease, oil, marking crayons, paint, and adhesive tape. Removal of organic contaminants is best accomplished by the use of a nonchlorinated solvent. It is important that nonchlorinated solvents be used. If a proprietary degreasing solvent is used, it should be tested to ensure that it does not contain chlorides. Residual chlorides remain in crevices and cause chloride SCC of austenitic stainless steels.

Weld Defects. Austenitic stainless steel surfaces can be affected by slag from coated welding electrodes, arc strikes, welding stop points, grinding marks, and weld spatter. These factors have initiated corrosion in aggressive environments that normally do not attack stainless steels. Arc strikes damage the protective oxide film of the stainless steel and create crevice-like imperfections in or near the HAZ. Weld stops create pinpoint defects in the weld metal. Arc strikes and weld stop points are actually more damaging than embedded iron, because they occur where the protective film has been weakened by the heat of welding.

Weld stop defects can be avoided by using runout tabs, by beginning the arc immediately ahead of the stop point, and by welding over each intermediate stop point. Arc strikes are more difficult to eliminate. Initially, the arc can be struck on a runout tab. It can also be struck on the weld metal when the filler metal will tolerate arc strikes. If the metal will not tolerate arc strikes, the arc must be struck alongside the filler metal in or adjacent to the HAZ.

Weld spatter creates a small weld in which the molten glob of metal touches and adheres to the surface. The protective oxide film is penetrated, and small crevices or pits are formed where the film has been weakened.

Heat tint formation also weakens the oxide film. The weakening is greater for some degrees of heating than for others, as indicated by the extent of color change. The necessity of removing heat tint is greatest where the environment is very aggressive and the stainless steel approaches the limit of its corrosion resistance.

Pickling by immersion in the standard HNO_3 -HF solution is the simplest and preferred method of heat tint removal when size permits. Glass bead blasting, using beads that are clean and of proper size in order to prevent overroughening of the surface, can also be employed to remove the heat tint.

Small slag particles from coated electrodes resist cleaning and tend to collect in slight undercuts or other irregularities. To remove slag from 300-series stainless steel, wire brushes fabricated from 300-series stainless steel should be used. For critical service, brushing should be followed by local pickling or glass bead blasting. Grinding is frequently used to remove slag, arc strikes, weld spatter, and other imperfections. Grinding wheels and continuous-belt grinders can overheat the surface and reduce corrosion resistance; therefore, they have limited usefulness. Abrasive disks and flapper wheels are not as harmful to the metal surface. Disks must be kept clean and replaced frequently. These procedures are good commercial fabrication practices and should be specified during the bidding and procurement stages in an effort to eliminate cost overruns and poor service performance.

Failures of Glass-Lined Steel Equipment

Most glass-lined equipment failures are not related to chemical deterioration of the lining but rather to mechanical and thermal influences. The typical failures encountered in the use of this type of equipment in the pharmaceutical and fine chemical industries usually involve mechanical shock, corrosion, abrasion, thermal shock, and thermal stress.

Mechanical shock is the most common cause of glass failure in pharmaceutical production facilities. It accounts for approximately 70% of the failures in glass-lined steel process equipment and is frequently the result of human error.

The most obvious cause of glass failure due to mechanical shock is objects falling on either the exterior or interior of the vessel. Care must be observed at all times when working near glass-lined equipment, because a shock to the outside of a vessel may cause damage to the glass lining.

Lifting lugs are normally supplied on glass-lining equipment and should be used for lifting the equipment and setting it in place. The lugs are specifically designed for this purpose and should be used in accordance with manufacturer's recommended procedures for handling and rigging. Shortcuts in rigging, such as using a nozzle as a lifting lug, can easily subject the glass lining to undue stress and cause damage to the lining. If mechanical shock has occurred or is suspected, the equipment interior should be inspected immediately and, if necessary, repaired.

Entering the interior of glass-lined steel equipment always creates a potential for mechanical

damage. In addition to compliance with the routine safety precautions, the mechanic should wear clean, soft rubber-soled shoes or sneakers to prevent scratching of the lining and should remove all loose objects from pockets prior to entering the lined equipment. Even metal belt buckles should be removed to prevent accidental scratching of the glass. Tools can be lowered to the mechanic when he is safely inside.

If it becomes necessary to remove product or by-products from the walls of glass-lined steel equipment, care must be taken to avoid scratching of the glazed surface. Metal tools should never be used. Plastic or wood scrapers can be used; high-pressure water jets are preferable.

The introduction of nucleated glass linings by fabricators of glass-lined steel equipment has reduced the damage caused by impact and, to some extent, has lessened its occurrence. Nucleated or partially nucleated glass linings have higher tensile strength and fracture energy than conventional glassed steel linings. These properties have lessened the tendency toward spalling from mechanical shock, the releasing of internal stresses, or thermal shock. Nucleated glass linings cannot prevent cracking entirely, but they tend to limit the extent of the damage by restricting it to a small area, usually requiring only a tantalum plug for repair.

Corrosion Attack of Glass Linings. Glass-lined steel is not completely inert and is constantly undergoing local chemical reactions at the glass surface. Glass-lined steel can be used with corrosive materials because of the low rate of reaction; the slower the rate, the longer the useful life of the glass lining.

Acids. Except for HF, concentrated H_3PO_4 , and phosphorus acid (H_3PO_3) above 85%, glass-lined steel is resistant to corrosion by acids. Generally, the corrosion rate decreases with concentration but accelerates with increasing temperature. Acid attack is more severe in the vapor phase than in the liquid phase, especially in more dilute solutions, because of the water vapor in the vapor phase. Usually, acid attack will result in a gradual loss of the fire-polished surface, but the lining will generally retain a dull, smooth finish.

Hydrofluoric acid will completely destroy glass-lined steel equipment. Even with concentrations as low as 20 ppm, fluorides in an acid environment corrode glass severely, especially in continuous reactions in which the fluorides are repeatedly replaced. Hydrofluoric acid reacts with silicon dioxide, the primary ingredient in glass, and destroys the silicon dioxide structure, forming silicon tetrafluoride and water vapor. The silicon tetrafluoride then hydrolyzes into silicon dioxide and hydrofluoric silicic acid, which are absorbed by the condensing water vapor. When this contaminated condensate reaches the heated vessel wall in the vapor space, it evaporates, depositing silicon dioxide and liberating the hydrofluoric silicic acid, which then disintegrates into silicon tetrafluoride and HF. The chain reaction keeps repeating itself

with continuous replenishment of HF. The corrosion occurs both in the liquid phase and in the cooler areas of the vapor space in which the fluoride vapor can condense.

Glass is not attacked by fluorine and its compounds in an alkaline environment, nor is it attacked by anhydrous hydrogen fluoride gas. The prerequisite for HF attack in the vapor space is the formation of water; thus, the corrosion rate will be greatly reduced if the vapor area is heated. In the liquid phase, fluorides will severely etch the glass and produce a roughened surface, with a complete loss of the fire-polished surface. In the vapor phase, the attack is more localized and concentrated; chipping and pinholes will be seen but with considerably less loss of the fire-polished glass surface.

Reagents that contain fluoride impurities must be carefully analyzed to determine the fluoride level before they are used. Frequently, technical-grade H_3PO_4 and its salts are contaminated with fluoride, as are other mineral acids. It is important to realize this when using these chemicals in recovery operations.

Alkaline attack of glass linings is much more severe than acid attack. The attack takes place only in the liquid phase in the case of nonvolatile alkalis. The greater the concentration and pH of the alkali, the greater the amount of corrosion. As the operating temperature and the pH increase, the corrosion resistance will decrease. Corrosion by alkalis is evidenced by pinholes, chipping, and a severe loss of the fire-polished surface.

Many glass-lined steel reactors have been lost prematurely in service by improper charging of reactants into the vessels. Caustic reactants charged into a vessel should always be fed directly into the liquid phase. If fed through a nozzle, the alkali will run down the sidewall of the reactor in the vapor space and cause severe alkaline attack, especially if the reactor is being heated.

Water can cause severe corrosion of glass-lined steel, and the severity increases with water purity and temperature, becoming greatest above the boiling point. When water droplets condense on the relatively cool surface of the glass-lined equipment in the vapor space, they leach out alkali ions from the glass and form an alkaline solution that attacks the glass. A small amount of acid added to the water usually slows the corrosion caused by condensation in the vapor space. This addition of acid is frequently useful in steam distillations. See the article "Rouging of Stainless Steels in High-Purity Waters" in this Volume.

Abrasion Failures. Failure of glass linings by abrasion alone is not very common. It is evidenced by a loss of fire polish of the glazed surface and results in a rough, sandpaper-like finish. Abrasion in conjunction with acid corrosion results in severe failure. The abrasive action weakens the silica network mechanically, allowing acid corrosion to accelerate rapidly.

Thermal shock failure occurs because of abrupt changes in the temperature of the glass

lining and results in relatively small but thick pieces of glass spalling off in rigid fractures. There are four operations in which sudden temperature variations can cause thermal shock:

- Sudden cooling of a glass-lined surface by subjecting a preheated surface to a cold liquid
- Sudden heating of a glass-lined steel wall by rapidly circulating a very hot fluid through the jacket of a cold vessel
- Sudden heating of the glass-lined steel surface by introducing a hot fluid into a cold vessel
- Sudden cooling of the vessel wall by rapid circulation of a cold fluid through the jacket of a preheated vessel

Thermal shock is strictly an operational problem and can be eliminated by adequate process controls. Unlike failure due to mechanical shock, thermal shock usually damages the glass lining so that repairs with tantalum plugs are not practical or possible. Reglassing of the vessel is then required.

Failure due to thermal stress is caused by differential heating or cooling that is not instantaneous. Thermal stress may occur on the vessel wall just below the area at the top jacket closure ring or in the area where the bottom jacket closure ring is welded to the vessel. In either case, the inside of the jacket can be heated or cooled, while the unjacketed area is not. At temperatures approaching 205 °C (400 °F), sufficient strain can be developed in the glass lining at these areas to cause the glass to crack. Thermal stress can be reduced by careful control of heating or cooling operations. Also, insulation of the unjacketed areas will help to reduce the extreme temperature variations.

Water hammer has also been known to cause shock waves that add to the thermal stresses at the area of the jacket closure. If these stresses are allowed to persist for long periods of time, cracks can develop with or without chipping.

Overstressing of Nozzles. Glass is strong in compression, but a concentrated point load can damage a glass-lined nozzle. The convex radius at the top of the nozzle also makes it susceptible to damage due to overstressing. The two situations that can cause overstressing of the nozzle and lead to possible failure are overtightening and overstressing by the attached piping.

Overtightening of bolts or clamps used to secure nozzles on glass-lined vessels to piping can cause glass lining to spall in large segments that may include a considerable area of the nozzle. Overstressing of nozzles through external piping can break the glass lining on the nozzle face. The design of external piping systems should include expansion joints or bellows as close as possible to the nozzles to minimize eccentric loads and moments and to allow for thermal expansion of the piping and the vessel. Cold springing when connecting pipe to a nozzle cannot be tolerated. Supporting heavy gear drives on a nozzle can also create an unsafe condition with regard to the glass lining.

Failures of Repair Plugs. Tantalum is the most commonly used repair material for glass linings. Its corrosion resistance is very close to that of glass, except in fuming H_2SO_4 above 65 °C (150 °F), H_2SO_4 above 98%, free sulfur trioxide (SO_3) above 65 °C (150 °F), or nascent hydrogen.

A repair made with tantalum will protect a glass-lined vessel for its useful life if the repair plug is installed in accordance with the recommendations of the manufacturer. However, the repair plug must be inspected periodically to ensure that it is secure.

Galvanic corrosion can cause hydrogen embrittlement of tantalum repair plugs, because the tantalum is in contact with the steel substrate. If a second dissimilar metal is present in the vessel, such as a metallic dip tube fabricated from a material other than tantalum, a galvanic cell is produced. Tantalum, being more noble, will generally act as the cathode where hydrogen is liberated.

Failure Due to Hydrogen Damage. Acids on the exterior steel surfaces of glass-lined steel equipment will, in time, react with the steel, forming nascent hydrogen. This hydrogen diffuses through the steel behind the glass and causes the glass to spall because of pressure buildup.

To avoid this type of failure, all acid spills on the outside of a glass-lined steel vessel should be washed off immediately to avoid acid attack. The so-called acid-resistant coatings give some degree of protection, but none is completely effective against acid attack on the steels.

Jacket cleaning can create another source of nascent hydrogen. The cleaning solutions recommended by the manufacturer should be used for cleaning the inside jacket of a glass-lined vessel. Strong acid solutions, inhibited or otherwise, should never be used for descaling the jacket, in order to avoid any possibility of nascent hydrogen formation.

Corrosion Beneath Thermal Insulation

Serious corrosion problems frequently occur under thermal insulation applied to vessels and piping components in pharmaceutical plants when the insulation becomes wet. Corrosion beneath insulation is an insidious problem that is also discussed in the article "Corrosion Under Insulation" in this Volume. The insulation usually conceals the corroding metal, and the situation can go undetected until metal failure occurs. The corrosion of metal components beneath insulation has led to very high maintenance costs and lost production time and has frequently required complete replacement of major components. In addition, operator and plant safety may be jeopardized.

Thermal insulation received from manufacturers and distributors is dry, or nearly so. Therefore, if the insulation remains dry, there is no corrosion problem. Possible solutions to

the problem of metallic corrosion beneath wet insulation include keeping the insulation dry or protecting the metal.

Unfortunately, the application of this solution is not that simple. Insulation can become wet in storage and during field erection. Moisture or weather barriers are not always installed correctly, or they are not effective in preventing water entry. Weather barriers and protective coatings can become damaged and are often not maintained and repaired.

The problem is further complicated by the fact that the degree of corrosion by wet insulation appears to be dependent on the insulation material as well as the atmospheric contaminants and moisture entering from external sources. Water extracts from calcium-silicate-base insulation, fiberglass, cellular glass, and ceramic fiber are generally neutral to alkaline, with pH values in the range of 7 to 11. Cellular glass is free of soluble chloride, while calcium silicate, fiberglass, and some ceramic fibers contain chlorides. Mineral wool gives a neutral environment when wet, usually a pH value of 6 to 7 with a low chloride content (2 to 3 ppm). Water extracts from organic foams can be quite acidic, with pH values of 2 or 3. In addition, where halogenated fire retardants have been added to the foam, water extracts show high levels of free halide, depending on the degree of hydrolysis achieved.

Carbon and low-alloy steels are normally passive in alkaline environments and have minimal corrosion rates. However, chloride ions (Cl^-), either from the insulation material itself or from airborne or waterborne contaminants, tend to break down the passivity locally and initiate pitting corrosion. If penetration by acidic airborne or waterborne contaminants of sulfur or nitrogen oxides is possible or if water extracts from the insulation are acidic, such as from organic foams, then general corrosion occurs. Occasionally, airborne or waterborne contaminants, notably the nitrate anion (NO_3^-), cause external SCC of nonstress-relieved carbon and low-alloy steel systems, especially if a cyclic wetting and drying concentration mechanism is present. Generally, plant facilities operating continuously or intermittently between 65 and 205 °C (150 and 400 °F) are subject to corrosive attack.

The most significant corrosion problem that occurs when insulated austenitic stainless steels are subjected to moisture is external SCC. The problem occurs because chlorides tend to concentrate under the insulation at the surface of the metal when the insulation becomes wet. The moisture can leach soluble chlorides out of the insulation, or the entering moisture may already contain chloride from the environment. At the warm metal surface, the moisture is vaporized, leaving behind an increasing concentration of chlorides. During operation, when the equipment or piping is in the susceptible temperature range, chloride SCC can then occur rapidly. The four factors necessary for SCC are an austenitic stainless steel, Cl^- ions, tensile stress on the

metal, and temperatures between 50 and 230 °C (120 and 450 °F).

Unfortunately, thermal stress relief, which is usually effective in preventing SCC of carbon and low-alloy steels, is normally not practical for austenitic stainless steels. However, there are numerous controllable factors in the design, construction, and maintenance of insulated equipment that have a marked effect on the amount of damage caused by corrosion under thermal insulation.

Equipment Design. The design of pressure vessels, tanks, and piping generally includes numerous details for support, reinforcement, and connection to other equipment. These details may include stiffening rings, insulation support rings, gussets, brackets, reinforcing pads, ladder brackets, flanges, and hangers. The design of equipment, including these details, is the responsibility of engineers/designers using construction codes to ensure reliable designs for both insulated and uninsulated equipment. Unfortunately, consideration of the problem of insulating these details and of leaving adequate room for the insulation is completely lacking in these codes and in the instructions to the engineers/designers. As a result, the items are designed as though they will not be insulated.

Undesirable geometries and design features include:

- Flat horizontal surfaces (such as vacuum rings)
- Structural shapes that trap water (H-beams, channels)
- Shapes or configurations that are impossible to weatherproof properly (structural members, gussets)
- Shapes that lead moisture and contaminants into the insulation hanger rods (angle iron brackets)
- Inadequate spacing that causes interruption of the vapor or weather barrier (nozzle extensions, ladder brackets, deck or grating supports). The weather barrier on such designs is frequently broken because of inappropriate details for insulated equipment or the lack of space for the specified insulation thickness.

The consequence of an incomplete moisture barrier is that more water and contaminants get into the insulation at each exposure cycle; this increases the time required for drying, cools the insulated equipment to temperatures at which corrosion is possible, and thus increases the damage. Some equipment details, such as gussets, brackets, and hangers, actually funnel water and contaminants into the insulation. Another consideration is the increased cost of insulating equipment that was not designed for insulation. In such cases, the insulation and jacketing must be cut and fitted by installers; thus, needless man-hours are spent insulating a complicated detail, with the result being an installation that is doomed to failure. The solution to such problems is to specify the type of insulation, thickness, and weather jacketing in the design stage.

The service or operating temperature of the equipment is very important in corrosion beneath thermal insulation. Higher temperatures make water more corrosive, and paints and caulking will fail prematurely.

Generally, corrosion associated with equipment operating below freezing temperatures is corrosion outside of, not under, the insulation. Equipment operating between freezing and the atmospheric dewpoint is subject to continuous corrosion, and damage can occur as quickly as it does under warm insulation. However, corrosion beneath warm insulation is more difficult to control, because of the drying out of water entering the insulation and the concentration of contaminants carried in with the water drying out repeatedly in the same location.

Insulation Materials. Corrosion is possible beneath all types of insulation. The insulation material is only a contributing factor. The insulation characteristics that are most influential in the corrosion of metal beneath insulation include water absorbency, chemical contributions to the water phase (not only from the insulation but also from external sources), and service temperature. Some of the more widely used insulation materials are discussed as follows.

Polyurethane foam is primarily used for cold and antisweat service. It does not absorb or wick water as long as the cell structure remains intact. It is permeable to water vapor in cold service when the required vapor barrier fails. Vapor diffuses through cell walls to the temperature zone in which it condenses and diffuses further to the point at which it freezes. The maximum service temperature is 80 °C (180 °F). If used in continuously cold service, it does not corrode unprotected metal surfaces. If in intermittent service to its maximum service temperature, it can cause corrosion of unprotected wet metal surfaces from released chlorides in fire retardants and blowing agents. The ultraviolet rays from the sun will decompose this insulation.

Polyisocyanurate foam is a fire-resistant organic foam having a low flame propagation rate. It does not absorb and wick water as long as the cell structure remains intact. It is permeable to water vapor in cold service when the required vapor barrier fails. The maximum service temperature is 120 °C (250 °F).

When polyisocyanurate is exposed to heat and moisture, the cell structure in the heated zone breaks down. The decomposition products may contain chlorides from the fire retardant and blowing agent and may aggressively corrode unprotected metal surfaces.

Flexible foamed elastomer does not readily absorb or wick water, and it has a maximum service temperature of 80 °C (180 °F). Although not corrosive by itself, it will support the corrosion of unprotected metal surfaces when water is present, especially when the water contains chlorides from an external source.

Cellular glass is a rigid glass foam whose blowing agent contains carbon dioxide and hydrogen sulfide. It does not absorb and wick

water. The maximum service temperature is 480 °C (900 °F). When water is present and the cell structure is damaged, release of the foam blowing agent may cause corrosion on unprotected carbon steel surfaces.

Glass fiber for insulation is usually a pure glass fiber containing various types of binders. Fiberglass will absorb and wick water; however, it drains excess moisture better than other types of insulation. The maximum service temperature is 230 °C (450 °F), with special formulations to 455 °C (850 °F).

Mineral wool is a natural mineral (rock wool) or metal slag fiber that is basically an impure glass. It readily absorbs and wicks water. Maximum service temperatures range from 650 to 980 °C (1200 to 1800 °F), depending on type and manufacturer. The fact that mineral wool will wick and hold water makes it a contributory factor in the corrosion of unprotected wet metal surfaces.

Calcium silicate insulation is a cementitious mixture and readily absorbs and wicks water. Calcium silicate insulation can hold up to 400% of its own weight in water without dripping. The maximum service temperature is 650 °C (1200 °F). Although its pH is initially high (10 average), it is aggressive in supporting corrosion on unprotected wet metal surfaces because of its moisture retention, particularly when the moisture contains chlorides from an external source.

Protective coatings are extremely important in preventing the corrosion of metal surfaces beneath thermal insulation. The assumption that a single coat of primer is adequate, based on the assumption that the weatherproofing never allows water to penetrate into the insulation system, is not valid.

Basically, service under thermal insulation is virtually an immersion service. Once the weather- or vaporproofing barrier is broken, metal surfaces under insulation are wet longer than the surfaces of most uninsulated equipment. Under warm insulation, the coating is subject to higher temperatures than most coated, uninsulated equipment. The coatings beneath thermal insulation fail because of chemical degradation and the permeability of the coating. Highly permeable coatings allow corrosion to initiate behind the coating film, even in the absence of breaks or pinholes in the coating.

In selecting a protective coating for use beneath insulation, consideration should be given to its abrasion resistance, temperature resistance, chemical resistance, and its ability to resist hot water vapors. Organic coating materials and surface preparation are discussed in details in the articles "Organic Coatings and

Linings" and "Paint Systems" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

In general, for carbon steel and stainless steel piping and equipment operating at -45 to 120 °C (-50 to 250 °F) under insulation, it is recommended that the surface be abrasive blast cleaned to NACE International No. 2 or SSPC: The Society for Protective Coatings SP10 near-white metal standards having a surface profile of 50 to 75 µm (2 to 3 mils). The freshly cleaned surfaces should then be coated with 305 µm (12 mils) (total dry-film thickness) of an epoxy phenolic coating applied in two or more coats or with 305 µm (12 mils) (total dry-film thickness) of a high-melting-point, amine-cured, coal tar epoxy applied in one or two coats.

For carbon steel piping and equipment operating at temperatures of 120 to 260 °C (250 to 500 °F) with intermittent cycling service into the hot water range under insulation, the same abrasive cleaning is recommended. The freshly cleaned surfaces should then be coated with 150 µm (6 mils) (total dry-film thickness) of a copolymerized silicone resin applied in two or more coats.

Carbon steel piping and equipment operating continuously above 260 °C (500 °F) under insulation should have the surface abrasive blast cleaned to NACE International No. 3 or SSPC: The Society for Protective Coatings SP6 commercial blast standards having a surface profile of 25 to 50 µm (1 to 2 mils). The freshly cleaned surfaces should then be coated with 100 µm (4 mils) (total dry-film thickness) of a black zinc-free modified silicone coating applied in two coats.

For stainless steel piping and equipment operating at temperatures from 120 to 370 °C (250 to 700 °F) under insulation, it is recommended that the surface be cleaned according to SSPC: The Society for Protective Coatings SP1 solvent cleaning standards. The freshly cleaned surfaces should be coated with 100 µm (4 mils) (dry-film thickness) of a black zinc-free modified silicone coating applied in two coats.

Inorganic and organic zinc-rich primers have given very poor performance under thermal insulation and should not be used. Possible reasons for this poor performance include:

- There is the likelihood of reversal of polarity of galvanic couples with increasing temperature.
- Chemical salts that are carried in and deposited with the water interfere with or destroy the effectiveness of the coating.

- The environment beneath the insulation is not freely ventilated and may not have adequate oxygen or carbon dioxide for film-forming reactions to occur.

Weatherproofing and Vaporproofing. The outer covering of the insulation system is critical. It is the principal barrier to the water necessary for the corrosion of metals beneath thermal insulation. Also, it is the only part of the insulation system that can be quickly inspected and economically repaired.

The purpose of the weather barrier, which should be used on warm or hot equipment, is to keep liquid out but to permit the evaporation of any moisture that gets in. The purpose of a vapor barrier is to keep both liquid and vapor out of the insulation system. Vapor barriers should be used on all cold and dual-service insulation systems.

Corrosion Effects on the Biocompatibility of Metallic Materials and Implants

Kenneth R. St. John, The University of Mississippi Medical Center

IN THE FIELD OF MEDICAL DEVICE DEVELOPMENT AND TESTING, corrosion of metallic parts can lead to significant adverse effects on the biocompatibility of the device. As corrosion occurs, the products of corrosion may accumulate in adjacent tissues; ionic species released may participate in metabolic processes as a substituent for the normal metallic ions in the processes and may impact the overall function of the device in its intended environment. Organometallic species may be formed by the reaction of proteins with the metals, inhibiting the normal function of the proteins. In addition, some individuals have hypersensitivity to certain metal ions that may produce localized or systemic immune responses.

In general, metals and metal alloys that have been qualified for use in medical devices achieve their compatibility through the formation of continuous passive films that prevent or significantly limit the corrosion rates encountered in the physiological environment. One mechanism of biocompatibility failure is the occurrence of conditions that damage the passive film or prevent its formation. Changes in environmental conditions surrounding the device, wear of moving surfaces, and fretting between components may all contribute to the loss of corrosion protection. In some cases, the increased corrosion may itself contribute to changes in the physiological environment and further corrosion problems.

All implanted metals release metal ions into the surrounding tissue and the tissues must then respond in some fashion. In general, the response is relatively innocuous and the metals are said to be biocompatible.

Origins of the Biocompatibility of Metals and Metal Alloys

As surgery for the repair of anatomical structures and the replacement of damaged organs and organ components have developed, a concern for the long-term survival of metallic devices and device components in the body has focused on both the damage to the components themselves

and injury to surrounding tissues and the body as a whole as a result of the presence of the metals in the physiological environment. Some of the concerns have included toxic responses to metallic ions released from the material, the long-term possibility of neoplastic transformations to cells and the development of cancer in response to the products of metal corrosion, and changes in the function of the material in the physiological environment as a result of the material/tissue interaction. As metals became more widely used in surgery, surgeons also wondered whether the appropriateness of certain metals could be determined in advance of their use and the long-term success of implantation of metals improved.

Mechanisms of Metal and Alloy Biocompatibility. It is almost universally true that metallic materials that are considered to be biocompatible or suitable for use in human implantation or tissue-contact device use derive their compatibility from the fact that they have a nonporous stable passive film on the surface that minimizes the diffusion of metal ions from the bulk material and prevents corrosion of the material in contact with human tissues. Based on testing results (Ref 1), it is clear that most of the alloying elements used in the production of the alloys used in surgery are not intrinsically inert, but the formation of the passive film protects the alloy from the corrosive physiological environment. Stainless steel and cobalt-chromium alloys rely on the presence of chromium in the alloy for their passivity. Titanium and its alloys rely on the titanium passive layer, and alloys containing zirconium rely on the zirconium passive layer. The biocompatibility of these materials is determined in vitro (outside the body) and in vivo (in the living body) under standardized and controlled conditions. In most cases, the breakdown of the passive layer on the metal surface is a major factor in biocompatibility problems with metallic devices. The absence or interruption of the passive layer removes the corrosion protection, at least temporarily, and leads to increased corrosion.

The usual response to the presence of metallic materials in living tissue is the production of a fibrous tissue capsule that surrounds the implant

and provides a partial barrier to physiological interaction with the metal and creates a micro-environment around the implant. In testing for acceptable biocompatibility, the thickness of the fibrous tissue capsule and the quantity and identity of the cells present in the surrounding tissues are compared with those for alloys with a long history of successful use with an acceptable tissue response. Some materials, most notably titanium and tantalum, can be implanted into tissue without the formation of a reactive fibrous tissue capsule (Ref 2–4). This characteristic is used in the implantation of titanium and tantalum into bone because, in the absence of micro-motion, the bone will grow back to the surface without an intervening soft tissue capsule, giving the potential for better mechanical stability of the device.

Early Studies of Metal Biocompatibility. Among the pioneers in the study of the tissue response to metals (*circa* 1930–1960) were Venable and his coworkers (Ref 5) and Laing (Ref 1, 6). Venable based his conclusions on observations from an animal study and concluded that pure metals were inert and, unless two dissimilar metals were connected, any reaction seen in tissues was purely a chemical reaction to body acids and had no electrolytic significance. He and his coworkers had observed extremely variable clinical results in the wide variety of metals and alloys being used at the time in surgery and were attempting to perform a scientifically based study to confirm for themselves which metals should be used in their patients. Their understanding of the electrochemical reactions occurring in their experimental animals was minimal, but it should be recognized that, in 1937, the general state of knowledge about corrosion and corrosion processes was much less understood. Venable did identify the need for consideration of the corrosion resistance of implant materials during the materials selection process.

Laing tested 42 alloys and 13 pure metals in rabbits to characterize the tissue reaction (thickness of reactive pseudomembrane) and the metal content in tissues surrounding the implant specimens. His results showed that some stainless steels (particularly type 316L and

precipitation-hardening type 17-7 PH) caused much less tissue response than the remainder of the stainless steels he tested. He recognized that physiological environments differ from the environments for which stainless steels were developed and were being used at the time. Therefore, test methods specific to suitability for use in the body would need to be developed. His observations of commercially pure titanium and titanium-aluminum-vanadium alloys gave evidence of the minimal response of the body to titanium and some of its alloys and, in 1967, preceded most of the research that has led to recognition of titanium alloys as particularly suitable for use in contact with bone. He found that the metals being used at the time for implant manufacture elicited a relatively minor response by soft tissues. Many of these same materials are still used in medical device manufacture. His observations of the response to pure titanium, zirconium, and niobium led him to suggest that they be considered for future development as alloy components, as occurred in the 1990s.

Failure of Metals to Exhibit Expected Compatibility

Metallic materials present in the human body are not subjected to uniform environmental conditions in all circumstances. The normal physiological environment may be generalized as pH 7.4, 0.9% (by weight) saline, at 37 °C (98.6 °F). These conditions vary in certain organs for metabolic or ion transport reasons (Ref 7), with the pH of gastric fluid as low as 0.8. The pH of urine ranges from 4.5 to 8.0 because of the role of the kidney in maintaining systemic pH. The pH in the microenvironment around dental caries-causing bacteria may be as low as 2.2 (Ref 8). During normal fracture healing, the pH of the local tissues has been found to decrease to 5.5 in the absence of infection (Ref 6). The same author showed a decrease to 5.5 and then an increase to 9.0 in the presence of infection. Others (Ref 9) state that infection results in decreased pH and decreased oxygen tension. A microelectrode study in 1988 (Ref 10) showed that pH under osteoclasts (the cells responsible for bone resorption) could be as low as 3.0 and under activated macrophages (cells involved in the response to bacteria and foreign materials), as low as 3.6. When an infection is present at the surgical site, the physiological response to the infection may include fever (a change in temperature systemically); a change in concentration of oxygen in the surrounding tissues; and inflammation, which will include a major local increase in defensive cells and a local increase in temperature. Because sodium chloride concentration, temperature, oxygen concentration, and pH can vary due to physiological needs, infection, and/or inflammation, the corrosive environment around the implanted metal may be significantly different from that under standardized testing

conditions. One report (Ref 11) suggests that the increased corrosion in the presence of infection may be self-perpetuating because the change in pH and the inflammatory response to the infection is a defensive reaction. In some cases, the increased levels of metal ions due to the higher rate of corrosion may lead to an immune response to the metal, and the initial inflammatory response to the infection may then become an inflammatory response to the corrosion products and metal ion concentrations, perpetuating the low pH and oxygen concentration conditions. Additionally, another study (Ref 12) showed that the presence of low levels of metal ions significantly reduced the ability of phagocytes to attack and kill bacteria, meaning that the infection can increase the corrosion rate and the corrosion products can serve to perpetuate the infection.

The details of device design (such as size, shape, and degree of conformity to surrounding tissues) and mechanical loading conditions introduce factors that may lead to physical breakdown of the passive film, such as fretting, erosion, or wear. Both particulate debris and metal ions are released into the surrounding tissues as a result of these processes. The tissue response to the products of corrosion may then exacerbate the conditions that initially contributed to the corrosion.

Dissimilar metals may be combined into a single tissue site either by design or, inadvertently, by the surgeon in placing devices composed of more than one component. Additionally, devices placed in close proximity to each other may become part of a complete circuit, even though it may not be immediately apparent that the necessary physical or electrical contact is formed.

Response to Severe Corrosion of Implant Metals. In the early days of the use of metals and metal alloys in surgery, selection of constituent materials was not necessarily based on their corrosion properties in 0.9 wt% sodium chloride solution. Surgeons or machinists with whom they were associated selected materials of construction and produced many of their own designs for solving clinical problems. In some cases, a great deal of corrosion occurred after implantation (Ref 13–15) and, in some cases, necessitated device removal and debridement (surgical removal) of surrounding tissues. In the first study (Ref 13), a type 316 stainless steel nail was attached to a type 303 stainless steel plate and the plate was then affixed to the bone with screws, some of which were 303 and some 316. Plates in the other two studies (Ref 14, 15) were both Lane plates, but after 29 years' and 64 years' implantation, respectively, the original alloy composition was not available and was difficult to determine on the highly corroded plates. The metallurgists who studied these plates found them to be similar to type 4068, a molybdenum-bearing low-alloy steel (Ref 14), or type 1060, a high-carbon steel (Ref 15), although compositional analysis of a severely corroded part is likely to be highly

subject to error. The surrounding tissues were found to be filled with considerable amounts of corrosion product, and there was a chronic inflammatory response to the corrosion products around the nail/plate and around the plate implanted for 29 years, but not the one implanted for 64 years. There was partial destruction of bone near the plate implanted for 29 years, which had been infected for 26 years. The plate left in place for 64 years was removed for reasons unrelated to the corrosion of the plate; the patient had been asymptomatic, and there had been no problems reported with the plate. Another example of tissue destruction due to the use of an alloy without the required physiological corrosion resistance is found in a case study from 1960 (Ref 16) in which the pitting corrosion of a fracture fixation pin (type 420 stainless steel), originally implanted in 1956, caused bone destruction and pain at the site of the deposition of corrosion deposits.

A cobalt alloy plate and screws (Ref 17) removed from a patient due to persistent pain were found to have failed due to crevice corrosion between the plate and bone. The composition of the plate was similar to that of Stellite 25 (Co-20Cr-15W-10Ni), although only 12.8% tungsten was detected in the alloy, while the screws were similar in composition to Stellite 21 (Co-27Cr-5.5Mo). The authors noted that the corrosion and corrosion deposits were associated with the plate and not the screws and that the patient's chronic pain was no longer present after surgery to remove the implants. Similar materials are still specified for use in medical devices and standardized through material specifications (Ref 18–20). Reports of corrosion problems and/or adverse tissue response with these alloys has been extremely rare and, while the cited case study serves to describe how tissues respond when corrosion occurs, it does not indicate a problem with the use of the alloys, but possibly with mixing the alloys.

In all except one of the cases cited, the surgeons reoperated on the patients because of chronic or intermittent pain associated with the corroded device and the pain was alleviated after removal surgery. It appears that one response to corrosion product is a painful inflammatory response at the site of the corrosion product deposits in the bone or other tissue.

Response to Particulate Materials. It is well known in the medical device literature that the response of tissue to the presence of particulate debris is increased levels of macrophages and other inflammatory cells in the area as the body attempts to fight off the foreign substance. When this response is due to bacteria, the response will result in the death of the bacteria; the death of the defensive cells that engulfed the bacteria and; over a period of time, a reduction in the inflammatory response to preinsult levels. While most of the studies of the tissue response to particles relate to the presence of wear debris around devices that have moving parts, particulate corrosion product may also be released from an implant site. When the

defensive response is to foreign particles, the initial response is the same but the particles remain after the reactive cells themselves have died and the tissue response is repeated or escalated. There appears to be a concentration of particles in the tissue that can be handled without long-term problems, but there appears to be a threshold concentration, which will vary from patient to patient, above which the tissue destruction due to the inflammatory response will make the process self-perpetuating. The response to the products of corrosion is the same as to wear particles and, in sufficient concentrations, will lead to tissue destruction around the corroding part. This type of response was reported in 1994 (Ref 21) in a study in which 15 explanted hip prostheses (ten at revision, five at autopsy) that had macroscopic evidence of corrosion were further evaluated, along with surrounding tissues. All had cobalt-chromium femoral heads and most of the stems were manufactured from the same alloy. It was found that most of the tissues contained corrosion product whose principal component was chromium and which was identified as chromium (III) orthophosphate hexahydrate. Lysis (destruction) of surrounding bone was seen in four of the cases and was the reason for device removal. The osteonecrotic (pertaining to dead bone) lytic lesions were inspected histologically and deposits of the corrosion product were found in all. It was not possible to say how much the corrosion products contributed to the failures because polyethylene wear particles from the acetabular cup bearing surface were also present. The corrosion particles were found to have been engulfed in phagocytic cells, suggesting that at least part of the osteolytic response was due to the corrosion product.

The presence of particulate corrosion products in tissues surrounding implanted devices has the potential to cause osteolytic problems, and some problems, which were originally considered to have been due to metal sensitivity (Ref 22), now appear to have been particulate related.

Metal Ion Leaching and Systemic Effects

There appears to be little question that serum and tissue metal ion levels experience an increase in the early postoperative period, particularly for total joint replacements, but most investigators have shown a decrease in metal ion levels after a period of time, although not always to presurgical levels. It also appears that, when the bearing surfaces are both metallic, instead of one of them being polyethylene, the metal ion increases are both greater and more sustained (Ref 23, 24). These studies showed that the metal ion levels in patients with metal-on-metal bearings were much higher than normal baseline levels of the metal ions measured before surgery or in patients without implants. Despite these findings, there is little evidence of long-term

adverse effects due to the levels of metal ions. Many of the original case reports describing elevated levels of metal ions and corrosion products around prostheses that failed due to loosening attribute the loosening to the metal ion levels and corrosion product in tissues immediately surrounding the prostheses. These studies were conducted before the wear of polyethylene was identified as the principal contributing factor to bone loss around implants, and before the presence or absence of polymeric particles was routinely reported. Given the black or gray color of metal products in the tissue, it is likely that polyethylene particles could be completely missed in these tissue samples. For this reason, case reports published before the 1980s must be considered with this fact in mind.

Metal Binding and Effects on Metabolic Processes. Most of the metal ions that may potentially be released from implanted devices are present at low levels in the normal physiology. In fact, many of these metals are essential for health. The normal physiological levels of metal ions in the body exist because of their role in many metabolic processes, and changes in their levels or specific chemical forms may adversely impact these normal functions, including the immune system and the functions of essential enzymes. Iron is a necessary part of hemoglobin, without which oxygen transport in red blood cells cannot occur. Vitamin B₁₂ is a cobalt compound and cannot exist without the presence of trace amounts of cobalt in the body. Cr³⁺ is essential to metabolic function, but, if Cr⁶⁺ becomes substituted in the organometallic compound, the compounds become nonfunctional. It was reported (Ref 21) that the corrosion products found were composed of trivalent chromium. The passive film on stainless steel and cobalt-chromium alloys is also trivalent chromium. One study (Ref 25) concluded, after laboratory and animal studies of DNA mutation, that trivalent chromium compounds are "relatively nontoxic and beneficial for human health." Another study (Ref 26), looking at laboratory studies of DNA damage due to trivalent and hexavalent chromium compounds, determined that Cr³⁺ was cytotoxic while Cr⁶⁺ was genotoxic. The authors further reported that Cr⁶⁺ is converted to Cr³⁺ in a three-step reduction in charge and suggested that the toxicity of the two forms are related. In most cases, the body can control the physiological levels of essential metals through ingestion and excretion, but at high enough levels, the metal ions can be toxic. There do not appear to be reports in the literature of systemic disease due to metal ion release from medical implants and chemical interaction with metabolic processes, but the acceptable levels of many of these metals are based on experience with industrial exposures through pathways other than direct absorption in the tissues.

Hypersensitivity to Metal Ions. One of the consequences of the release of metal ions from an implanted device is the potential for an

allergic response to the metal. One of the most common examples of hypersensitivity is the body's reaction to nickel. Nickel is present in the stainless steel commonly used in fracture fixation devices and other implantable devices (for example, 13 to 15% Ni in type 316L implant-grade stainless steel). Many persons, particularly women, are sensitive to nickel ions and can develop a reaction to the presence of stainless steel devices under the skin, as commonly occurs in devices used for the stabilization of fractured bones while awaiting healing. This type of response does not usually occur at the first exposure to the allergen but rather is a response that increases as a result of repeated exposures to the metal ions. Women are much more commonly exposed to stainless steel in jewelry such as earrings for pierced ears, and thus the likelihood of a response to an implanted alloy containing nickel is much greater. Some patients who might be susceptible to an immune response to nickel may previously have experienced inflammation around earrings or under wrist-watches. Sweating around and under stainless steel jewelry will create a corrosive sodium chloride environment that may be conducive to corrosion of the alloy in the jewelry. The reaction to nickel has been considered enough of a concern that stainless steel alloys with little or no nickel content have been developed for implant use and are being used in some applications (Ref 27, 28). Table 1 lists chemical composition requirements for low-nickel implant-grade stainless steels as well as conventional (higher-nickel) grades used for fracture fixation devices. Reactions to other metal ions are reported less frequently, but there have been reports of sensitivity to chromium (Ref 29), cobalt (Ref 29, 30), and gold (Ref 31–33); however, these seem to be of lesser concern.

A recent clinical study (Ref 34) documented preoperative metal sensitivity to at least one component of a commonly used cobalt-chromium alloy (UNS R30075, Ref 19) in 26% of 92 patients before surgery to implant a total knee replacement. Five of the patients developed eczema at the surgical site or extending over the whole body. Two of those patients had their implants replaced with devices made of ceramic and experienced resolution of symptoms, providing strong evidence for the implant being the source of the problem. While patients are not routinely screened for allergies to the metals present in medical alloys, these authors recommended such screening (Ref 34). Five out of the 24 patients who showed a metal sensitivity actually experienced reaction to the metal ions after surgery. The remaining 19 patients, with equivalent scores in the sensitivity testing, did not exhibit a response after surgery. One of the problems to be addressed in this area is the fact that clinical decision making based on the results of testing that is only about 20% predictive could lead to the needless elimination of patients from consideration for certain types of medical devices that have the potential for improving quality of life.

Possible Cancer-Causing Effects of Metallic Biomaterials

There has been a concern that the release of metal ions or corrosion products in the tissues surrounding medical devices might induce mutations in the cellular DNA and eventually lead to the development of malignant tumors. Considering the large number of metallic devices that have been implanted over the last 75 years, there does not appear to be an epidemic of malignant neoplastic transformations around medical devices, but individual reports of tumors adjacent to metallic implants have been published.

Studies have shown that sufficient quantities of some metal ions will produce changes in cells that could lead to the development of cancer tumors. An *in vitro* study of cobalt in fibroblast cell culture (Ref 35) found changes in nuclei and cells division in daughter generations of rat fibroblasts exposed to cobalt chloride as compared with daughter generations of cells not exposed to cobalt. The large quantity of metal that may be necessary to elicit cellular changes does not provide useful information about the possibility of cellular changes at the much lower concentrations and dosages that are likely around implants manufactured from commonly accepted alloys. The suitability of commonly accepted alloys is primarily due to their corrosion resistance in the physiological environment.

Recently, the resurgence in the use of metal-on-metal articulations in total hip prostheses has revived questions about the potential impact of metal ions on cells at the chromosomal level. The very low wear rate of these articulations (less than 1 mg per million cycles) means that the wear primarily results in the removal of the passive layer from the polished surfaces, followed immediately by repassivation, a process similar in mechanism to fretting corrosion. A clinical trial in Italy (Ref 36) showed no correlation between chromosomal changes in peripheral lymphocytes and metal ion concentrations in 30 patients six months after surgery. Another study (Ref 37) showed chromosomal changes in 31 total hip replacement patients at the time of removal of a failed prosthesis, as compared with 30 primary hip replacement patients. Neither study reported the development of any malignancies in study patients but both recommended

continued study because the types of chromosomal changes being reported have the tendency to be cumulative and have long-term effects.

Tumors have been found in close proximity to implanted metallic devices as reported in papers published between 1967 and 1997 (Ref 38–51) in which tumors were suspected to have a relationship to metal ions or corrosion product released from devices. Each report discusses only one or two patients and represents a very small percentage of all devices placed into patients during the time periods in question. Only two of these reports (Ref 47, 48) appear to deal with prostheses in which there was deliberate movement of two metallic surfaces against each other (metal-on-metal hip prostheses), which holds the potential for increased release of metal ions with repetitive repassivation as wear occurs. Additionally, in a study of 1358 patients for up to ten years, cancers of the lymphatic and blood cell production tissues were significantly higher in patients with implants than those without implants (Ref 52). Tumors of the breast, colon, and rectum were significantly less than expected. The conclusions suggest that there may be an association with the prostheses but that other factors, such as drug therapies used, should also be considered before a direct correlation is assumed.

Neoplastic and carcinogenic effects of chemicals in the body are frequently a response to long-term exposures to low levels of chemicals in the body, and any determination of these effects requires long-term epidemiological studies to confirm a direct relationship. Except for tissue destruction in response to particulate corrosion products and allergic responses to metal ions, tumor formation in association with metallic medical devices appears to be one of the few theoretical adverse effects of corrosion that has had reports of its actual occurrence in human patients. If this problem were common and widespread, there should be a great deal more reports of the problem than currently exist. Since these first reports appeared, there have been hundreds of thousands of metallic device implantations with very few additional reports. In addition, many devices already implanted at that time continue to be present in living patients, extending the period of exposure to the patients.

Summary

The metallic materials used in surgery currently derive their biocompatibility from the alloying elements responsible for the development of continuous stable passive layers on the surfaces. There is a very low level of release of metal ions even under the ideal conditions of passivity and when there is no damage to the surfaces. Corrosion of these metals and alloys may occur when environmental conditions change, when mechanisms for repetitive surface damage occur, or in rare situations in which dissimilar metals are used in an inappropriate combination. Case reports and data from the use of other alloys in the period before about 1965 show the possible adverse tissue effects when corrosion products are released in the surrounding tissues. These early results were the basis for controlled animal studies to try to identify which alloys were the most appropriate for implantation based on the tissue response to the corrosion products from the alloys. As standardization has occurred and government regulatory bodies have begun to regulate these devices and the materials of manufacture, the experience of previous generations has been brought to bear, and the corrosion of metallic medical devices has become more uncommon.

The potential adverse effects of metal ion release into living tissues can be described based on information from industrial exposure, pollution, and other exposures to high or extended doses of metal particles and dissolved metal ions. Testing in the laboratory and in animals has occasionally produced results that, while of concern in the initial reporting, do not appear to be borne out based on clinical experience. The results of laboratory tissue and cell culture testing as well as the testing of simulated failure products *in vivo* do not necessarily take into account all of the protection mechanisms and physiological response characteristics of the actual implant usage situation. Potential mechanisms of long-term adverse responses do exist and the continued monitoring of clinical results is occurring. While some proposed problems, such as tumor formation around devices or toxic responses to metal wear particles, have not been seen to have occurred in sufficient numbers to be proved to be anything other than

coincidental, longer-term data collection on the increasing numbers of devices in use may provide additional data to prove or disprove the theories.

It is clear that when corrosion occurs, the consequences to the surrounding tissues can be quite severe, but research, government regulation, and consensus standards for both biocompatibility testing methods and for the composition of metals and alloys suitable for use in surgery have improved the likelihood that metallic medical devices will be present in the physiological environment without significant corrosion and adverse consequences.

Mechanically Assisted Corrosion of Metallic Biomaterials

Jeremy L. Gilbert, Syracuse University

METALLIC BIOMATERIALS have been used for the past several decades in a wide array of applications spanning several medical and dental fields. Much early work in metallic biomaterials was performed in the dental community where gold alloys, dental amalgams, and base metal alloys of cobalt, nickel, and iron have been used. More recently, the use of titanium has increased dramatically in dental applications such as dental implants. Metal alloys have been used in orthopedic applications in greatest amounts related to fracture fixation devices and total joint arthroplasties. Alloys of cobalt, titanium, and iron also have been used in cardiovascular applications such as heart valves, stents, and pacemakers. In spinal applications, metallic alloys are also used in significant quantities where adaptations and innovations from the fracture fixation field have evolved into a set of highly specialized designs for spinal instrumentation (e.g., pedicle screws, fusion instrumentation, etc.) Most of the earlier designs and devices used in spinal instrumentation were made from iron-base alloys (type 316L stainless steel, ASTM F138) (Ref 1), but more recently other alloys are being explored, alone and in combination, due to the current understanding of each material's behavior and interaction with the biological system. There is an increasing complexity in designs being developed where multiple screw-countersink combinations, rod-set screw designs and other crevicolike and restricted environments are developed. Here, restricted means locations where small volumes of fluid can be relatively isolated from the bulk solution environment and where possible chemical reactions may alter the chemical makeup of this fluid (e.g., make it more concentrated in metal ions, lower pH, etc.).

Questions may arise as to what combinations of metal alloys can be used and in what types of designs such that there are no untoward effects on the patient. In particular, there are concerns that combinations of dissimilar metals may result in adverse corrosion reactions, leading to negative consequences.

The goal of this article is to review the current understanding of the corrosion interactions

between alloys, in particular iron-base, titanium-base, and cobalt-base alloys, in complex geometries and in applications where there are significant cyclic stresses and potential for wear and fretting motion. This review attempts to frame the nature of these metal surfaces, their propensity for corrosion reactions when combined with similar or different alloys in complex restrictive (e.g., crevicolike) environments within the human body, and under loading conditions.

Iron-, Cobalt-, and Titanium-Base Biomedical Alloys

Stainless Steels. The main alloys used in orthopedics and spinal instrumentation today are the iron-base alloys (low-carbon type 316L stainless steel; ASTM F 138, Ref 1), as well as newer alloys with low nickel and high nitrogen- and manganese-containing alloys, e.g., ASTM F 1586 (Ref 2), and F 2229 (Ref 3), respectively. These alloys (primarily vacuum melted type 316L stainless steel) are austenitic, single-phase alloys and have served as plates, screws, nails, rods, and wires in a wide array of applications. Their strength and corrosion resistance are very good, although alloys based on titanium and cobalt-chromium have better corrosion and mechanical properties and have been making inroads into uses where type 316L had typically been used.

Cobalt-Chromium Alloys. These alloys come with a variety of chemistries that fall under the range of cobalt-base alloys. There are several ASTM designations for these alloys, including F 75 (Ref 4), F 799 (Ref 5), F 1537 (Ref 6), and so forth, which include Co-Cr-Mo, Co-Cr-Ni-W-Mo, and Co-Cr-Ni-Mo alloy systems. These have been used in cast, wrought, and forged conditions and, more recently, as powder metallurgy products that are sintered into net shape. These alloys have a complex metallurgy (Ref 7), with multiple phases possible and present depending on the fabrication process, including complex carbides. The chemistry may vary somewhat within the microstructure as well

as due to chemical heterogeneity during solidification or processing.

Titanium and its alloys have enjoyed widespread use in biomedical applications either as commercially pure (CP) titanium, ASTM F 67 (Ref 8), F 1341 (Ref 9), as well as alloys including Ti-6Al-4V ELI, ASTM F 136 (Ref 10) and others. More recently, alloys of nickel and titanium have been developed to take advantage of the super elastic and shape memory characteristics of this alloy (ASTM F 2063) (Ref 11). Titanium has very good mechanical properties and corrosion properties (in the absence of surface mechanical abrasion) and is known to be highly tolerated in the body environment. In fact, titanium has taken on the aura of being the "most biocompatible" metal in use today. There are a variety of rationales for this primarily linked to the relative inertness of the alloy surface. However, recent work indicates that there may be other factors that influence its behavior, including semiconducting properties, catalytic activity, and the relatively high electric field conditions that exist at its thin oxide film surface (Ref 12–14). More details are presented in a companion article, "Corrosion Performance of Stainless Steels, Cobalt and Titanium Alloys in Biomedical Applications," in this Volume.

Surface Characteristics and Electrochemical Behavior of Metallic Biomaterials

The surfaces of iron-, cobalt-, and titanium-base alloys have some similarities (and some differences) that are worthy of mention. One of the main reasons that each of these alloy systems is in such significant use today is due to their corrosion resistance within the environment of the human body.

The main factor governing the corrosion resistance of medical alloys is the presence of a nanometer-scale oxide film that spontaneously forms on the surface. These oxide films provide a kinetic barrier to corrosion. That is, each of these alloys has a high free energy driving oxidation of

the metal components and each would corrode at extremely high rates if the oxide film were not present to limit specific steps in the corrosion reaction (Ref 15, 16). However, the oxide films that form act to limit access of the metal to the environment and the environment to the metal such that continued oxidation/corrosion is greatly reduced. The importance of these oxides to the continuing resistance to corrosion cannot be understated. It is also important to understand that high thermodynamic driving forces for corrosion are present and remain even in the presence of these oxide films and these forces, which manifest primarily as an extremely high electric field across the oxide, continue to attempt to drive corrosion and assist in several processes, including ion migration (chemical segregation) and electronic charge transport.

One of the most important aspects of the corrosion resistance of each of these alloy systems is the integrity of the oxide film. If, for whatever reason (mechanical abrasion, chemical effects, biological effects), the oxide films are compromised, then the high driving forces for corrosion will take over and severe, high-rate corrosion can and will take place. This has been documented in several ways in the literature and is discussed subsequently. Oxide films are not, in a literal sense, films *per se*, but rather they can take on a variety of morphologies including domes, overlapping domes, oriented elongated domes, and film-dome combinations. The details of the oxide morphology on the surface is also affected by surface treatments, prior electrochemical history, and immersion time. These effects are also reviewed in the article, "Corrosion Performance of Stainless Steels, Cobalt and Titanium Alloys in Biomedical Applications," in this Volume.

A large body of literature exists on the electrochemical behavior of these alloys in physiologically representative solutions. Corrosion testing has been performed in 0.9% sodium chloride (NaCl), phosphate buffered saline (PBS), Ringer's solution, Hanks' balanced salt solution, and a variety of other solutions that vary in complexity (e.g., protein additions, aerated/deaerated, etc.), as discussed in the aforementioned companion article in this Volume. All of these alloys show fairly high corrosion resistance over a range of electrochemical potentials when performing polarization testing. These types of corrosion tests are helpful in understanding the corrosion behavior of alloys in the absence of mechanical factors (i.e., where the oxide films are not stressed or abraded) but have a limited value in understanding the true nature of the surface behavior. Typical results from these tests cannot always tell the range of potential where the oxide is stable, whether oxide reduction is possible, what type of breakdown occurs at anodic or cathodic potentials (e.g., pitting vs. generalized corrosion, corrosion inside a crevice, etc.), and what level of corrosion is obtained at these surfaces in the absence of mechanical factors. Standard electrochemical testing (anodic polarization testing, cyclic polarization testing, etc.) is also not able to provide insight into the

effects of combining components (or different alloys) or understanding how surface abrasion or fretting-crevice corrosion may impact the corrosion stability.

Standard electrochemical tests are also limited in providing insight and knowledge about medical devices that may be made of various alloys, combined and connected with potential crevices, and the possibility that they may be cyclically loaded and stressed. Under these types of geometries and mechanical loading states, corrosion becomes a much more complicated process. This requires that we develop new ways of thinking about medical device corrosion in the presence of mechanical factors.

It should also be mentioned that most electrochemical testing of biomedical alloys has been done in environments that, at best, represent the body environment in a highly simplified manner. Most testing is done at neutral pH with normal physiological ionic concentrations of inorganic salts (e.g., PBS, NaCl, etc.). Little work has been done to investigate the complex environments that arise either as a result of local biochemical changes (e.g., local inflammatory reactions at a metal surface due to the presence of inflammatory cells and wound healing) or the restricted environments that may arise in the geometrically complex implants that are being designed. In this context, solution chemistry can be highly different from the pH 7.4 saline solutions typically used in corrosion experiments including superoxide radicals and their by-products (e.g., peroxynitrite, hydrogen peroxide), pH as low as 1, high local levels of metal ions, proteins, and lytic enzymes whose effect is unknown.

The Clinical Context for Mechanically Assisted Corrosion

Since the early 1980s there has been an increasing awareness of the development of mechanically assisted corrosion in orthopedic and other medical device constructs. Early work in fretting corrosion (Ref 17–19) and fretting corrosion fatigue (Ref 20) have focused on nails, plates, screws, and screw-hole countersink interactions. Since the late 1980s, the development of implant modularity has been the primary reason why mechanically assisted corrosion processes have become a significant concern. Implant modularity is where different components of a total joint prosthesis are combined, for example, at the time of surgery using metal-metal conical taper connections that the surgeon assembles. These conical tapers are sometimes referred to as Morse, or modular tapers (see Fig. 1 for an example). Many advantages have been identified for the use of modularity that makes this design approach an important advance. Modularity provides surgeons with greater flexibility intraoperatively to make the right choice of components. Different alloys can be used for different aspects of the prosthesis

(e.g., titanium alloys for the stem of the hip replacement, due to better bone biocompatibility, and a cobalt-chromium alloy for the head, due to better wear resistance). Also, modularity allows for a large number of combinations of designs to be available with much fewer parts needed for manufacture and hospital inventory. Finally, modularity provides greater flexibility during revision surgery to replace portions of a device without having to remove and replace the entire prosthesis.

Early studies of corrosion in conditions similar to modular implants included investigations into the corrosion behavior of assemblies of alloys and mixed alloys with crevices (Ref 21–26). These studies showed little evidence that mixing alloys or the presence of crevices would have a deleterious effect on the corrosion behavior. However, early reports (Ref 27–29) of femoral stems of total hip prostheses that were retrieved during revision surgery (i.e., after implantation, used for a period of time, and then removed due to such complications as loosening, infection, pain, and other causes) showed some evidence that significant corrosion attack was taking place at the modular junctions of these devices. These early reports focused mostly on the idea that mixed alloys were causing a galvanic attack since the combinations reported on were Ti-6Al-4V stems connected to cobalt-chromium-molybdenum heads. However, other studies (Ref 30–36) around the same time began to show that corrosion within these modular tapers was not limited to dissimilar metal combinations (Fig. 2). Corrosion was also observed in cases of cobalt-chromium stems with cobalt-chromium heads, and titanium stems with titanium heads (Ref 30, 33).

More recent work has shown that modular connections in a wide variety of devices, for example, intramedullary rods (i.e., rods that are placed in the center canal of long bones) and revision hip stems with modular connections, are susceptible to corrosion attack (Ref 37–39) and that severe corrosion can be observed even with type 316L stainless steel or titanium-titanium interfaces (Fig. 3).

Retrieval studies (Ref 40) have shown that modular taper corrosion appears to be linked to the mechanics of the taper. Tapers with low flexural rigidity (small diameter tapers made from low modulus materials, e.g., titanium) show a higher probability of being corroded at the same time after implantation than high rigidity materials and designs. Also, the materials combination appears to play a role, with titanium stems in contact with cobalt-chromium heads having a higher extent of corrosion and a greater probability of corrosion compared with cobalt-chromium/cobalt-chromium combinations. Stainless steel alloys, as well as titanium-titanium junctions have also been shown to be susceptible to corrosion at the modular taper (Ref 38) as shown in Fig. 3.

Thus, the findings from these studies have demonstrated that when devices are implanted with modular connections, there is a significant

probability that corrosion will occur at the taper interface. The probability of corrosion in modular connections in hip prostheses is between 28 and 42% in retrieved cases with factors affecting this rate being materials combination, flexural rigidity, and time of implantation (Ref 40). How these percentages relate to the overall population of femoral hip prostheses is not known. However, there are two possibilities: either the corrosion process has affected the reason for retrieval, and hence the rates seen are higher than the overall population, or the corrosion process has not influenced the rate of revision. If it is the first case, then this is clear evidence that corrosion is a clinically significant process (having raised the revision rate). If it is the latter case, then the percentages seen in the retrieval studies are a reflection of the overall rate of corrosion in the population of modular devices. This would imply that the corrosion process occurs at very high rates in modular connections. It is important to note that this corrosion process occurs in all

passivating alloys used in orthopedics and that there are mechanical factors that influence its occurrence.

The main reason why corrosion in modular connections was not foreseen prior to their introduction is that virtually all corrosion testing of these alloys had not included mechanical loading as part of the test. These devices experience high cyclic mechanical loads and stresses that are complex and variable. Typical loading forces in total joints can be several times the weight of the patient, and normally active patients will load their legs on the order of 1 to 2 million cycles per year. When these mechanical effects are included, then corrosion of passivating alloys becomes very much a reaction to electrochemical driving forces in conjunction with mechanically driven oxide disruption processes. Thus, to understand the electrochemical behavior of metallic medical devices, the mechanical environment should be included in any evaluation of their performance.

Other reports of corrosion attack include evidence of a mechanically assisted crevice corrosion attack of cemented stems of total hip prostheses (Ref 38, 41, 42). It was found (Ref 41) that upon revision surgery, the pH of the solution present at the interface between the stem and the orthopedic bone cement holding it in place was significantly lower (around 3) than the physiological pH normally assumed (pH 7.4). The researchers also noted that pain was associated with severely corroding and low pH cases. Pitting and crevice attack of cemented stainless steel hip stems has also been reported (Ref 38).

There are other clinical ramifications to this corrosion process. For instance, there have been reports of fatigue failures emanating from corroded taper connections (Ref 32). Also, corrosion by-products, which include particles and ions, can be released into the local tissue and can cause osteolysis (a cellular-driven process of "bone destruction" that leads to lesions in the bone), and can be systemically distributed via the bloodstream. Particles have been found in lymph nodes removed from the implant site as well as in such organs as the liver, spleen, and kidney. Blood and urine levels of corrosion by-products (e.g., Co ions and Cr ions) have been identified in patients with modular tapers that are corroded and the level is correlated to the severity of corrosion (Ref 15, 37, 42–47).

There are other devices that are susceptible to mechanically assisted corrosion, for instance, vascular stents, which are small-scale wire mesh (much like chicken wire) tubes typically made from type 316L stainless steel or NiTi shape memory alloys. These stents are inserted on a catheter to the intravascular site (inner lumen) to provide structural support to prevent restenosis (renarrowing) of arteries with atherosclerotic plaques. These stents are inserted in a compressed (small diameter) state and then deployed by expanding the stent and deforming the wires. This deformation results in breaches on the oxide film and transient high corrosion rate processes that cause significant local currents and large drops in open circuit potential (OCP) of the stent. An example of the OCP drop during deployment of a type 316L stainless steel stent is shown in Fig. 4.

Mechanically Assisted Crevice Corrosion

From these clinical and retrieval reports a better understanding of the specific factors that give rise to the observed corrosion behavior has been obtained. Specifically, questions arose about the possibility of galvanic attack and about what role mechanical factors had on the process. Because evidence of corrosion was found even where the alloys at the taper interface were chemically identical, galvanic effects, while still a potential contributor, could not entirely explain the presence of this corrosion process. Thus, mechanical factors were explored in more detail.

Over the past decade, ideas related to corrosion of medical devices in biological

Fig. 1 Optical photographs of modular tapers from a variety of prostheses showing evidence of corrosion. (a) Cross section of a retrieved modular femoral component for a total hip replacement. The head comprises Co-Cr-Mo alloy and the stem is a Ti-6Al-4V alloy. The taper interface is revealed by sectioning. (b) Retrieved Co-Cr-Mo modular head that had sat on a Ti-6Al-4V stem. Note the dark and discolored region inside the taper recess and signs of etching. (c) Taper junction (both male and female portions) of a 316L stainless steel intramedullary rod after retrieval. (d) Retrieved Ti-6Al-4V neck and Ti-6Al-4V "thimble" (sectioned in half) used to attach a ceramic head to the femoral stem. Two modular interfaces are established in this design, one comprising the Ti-Ti junction and the other the Ti-ceramic junction. Note the interface regions are highly corroded on both Ti interfaces and a purple color was present (lighter gray in black-and-white, indicative of Ti^{3+} ions). Also found at these interfaces is evidence of Ti-phosphate particles, which indicate that the pH had dropped below 1 inside the taper.

environments in the presence of mechanical factors have been clarified with a series of articles (Ref 16, 48–59). These articles have investigated the clinical aspects of mechanically assisted corrosion, experimental testing of the mechanism in vitro, and testing of the basic aspects of oxide disruption and reformation. Mechanically assisted corrosion as a term is not widely used; however, it captures a range of possible mechanisms that are considered by the general corrosion community. Mechanically assisted corrosion encompasses all mechanisms that combine mechanical factors with electrochemical factors to increase the rate of corrosion. Effects such as fretting corrosion, corrosion fatigue, wear-assisted corrosion, stress-assisted corrosion, stress-corrosion cracking fall under

this more general term. Also part of this model is the restricted (or crevice-like) environment that can serve as the location for significant changes in local solution chemistry. Thus, mechanically assisted corrosion can and often does occur in crevice-like environments. The essential feature of mechanically assisted corrosion processes is that alloys with oxide films that serve as kinetic barriers to corrosion (i.e., are passive films) will experience dramatic increases in corrosion rate when exposed to mechanical factors that can disrupt (or distort) these oxide films. With increased corrosion rates can come other changes in terms of the stability of the oxide film, shift in potential, local consumption of oxygen, decreasing pH, and so forth, all of which can affect (or feed

back) to the mechanically assisted corrosion process.

The mechanism of mechanically assisted corrosion comes about from the fact, as mentioned previously, that oxides provide a barrier to corrosion and that disruption of this barrier will significantly alter the corrosion behavior. The features needed for mechanically assisted corrosion are: (1) a passive film-covered alloy (e.g., type 316, cobalt-chromium, titanium, etc.), (2) mechanical stress and/or abrasion sufficient to disrupt the oxide film typically in a cyclic fashion, and (3) an aqueous electrolyte. Additionally, if there are restricted geometries where fluid ingress and egress are limited (e.g., crevices, screw-countersink interfaces, implant-bone cement interface, etc.), then these crevice-like environments can provide a set of additional factors that may predispose these alloys to aggressive and severe attack.

The mechanism of mechanically assisted corrosion is as follows. Figure 5 gives a model of the femoral component of a modular total hip replacement head-neck junction (at left). At higher magnification, the head and neck come together at the conical taper interface (center). However, the contact surfaces are not perfectly matched and are sometimes machined to give high and low points in the cross section and, therefore, engage in asperity-asperity contact. These geometric gaps provide locations for fluid ingress into the interface region between the two surfaces. During loading, small-scale cyclic motion (fretting) can take place at this interface that, if the contact stresses are large enough, can result in disruption of the oxide film by the counterface (right).

Once the oxide film is breached or disrupted (or stressed), dramatically larger corrosion currents are generated as this breached film area reforms new oxide film. There are two major sources of Faradaic (corrosion-related) currents (or current densities, current per unit area) during this disruption event (Fig. 5, lower right). One gives rise to ionic dissolution currents ($i_{\text{dissolution}}$), and the other to film formation currents (i_{film}). The current density during these periods of oxide film disruption can be many orders of magnitude higher than the currents measured at nondisrupted oxide film covered surfaces. For example, typical current densities for oxide film covered alloys of titanium, cobalt-chromium, and type 316L are in the range of 0.1 to $5 \mu\text{A}/\text{cm}^2$ when there is no mechanical disruption. However, currents across disrupted oxide film surfaces can reach up to 5×10^5 to $1.5 \times 10^8 \mu\text{A}/\text{cm}^2$ (Ref 49, 51, 56, 60–66). That is a roughly 10^6 to 10^8 increase in current density that results when an oxide film is disrupted.

Some of this current goes to form new oxide film that then acts to shut down the corrosion reactions. Figure 5 shows a differential equation that describes the relationship between the total current transient, i_{total} , and the film and dissolution currents. This model, adapted from Ref 67, assumes that at any instant after disruption, there is a fraction of the volume of oxide removed that

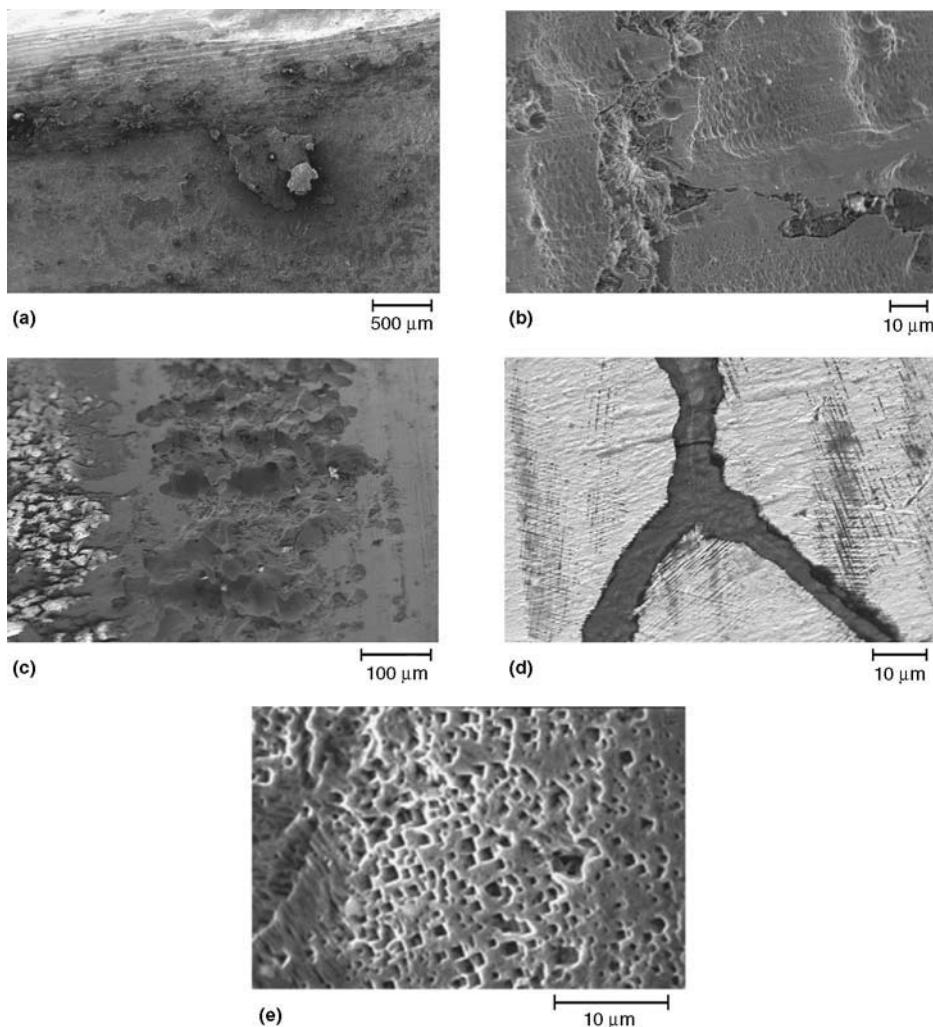

Fig. 2 Selected scanning electron micrograph (SEM) micrographs of retrieved modular connections from different orthopedic implants showing evidence of corrosion attack. Buckley, Ph.D. thesis, Northwestern University, 1994

has reoxidized from the bare metal (θ), and a fraction that has not ($1 - \theta$). The ionic dissolution currents are assumed to occur only in the non-reoxidized regions and to obey a Tafel-like behavior. In Fig. 5, ρ is the oxide film density, V is the volume of film removed, n is the charge per cation, F is Faraday's constant (96,480 C/mol), M_w is the molecular weight of the oxide, i_{odiss} is the dissolution exchange current density, η is the

overpotential for active dissolution, A_o is the area scratched, b_a is the anodic Tafel slope, and τ is a time constant for repassivation. One can readily solve this equation if one assumes that the total current behaves according to an exponential decay process (Ref 49). Experiments have shown this to be a good approximation (Fig. 6). Film reformation can take place quickly or it can take a significant amount of time depending on the

specific circumstances. In a typical environment and at a "normal" fixed potential, repassivation rates are on the range of a few milliseconds; however, this can be affected by pH, potential, and the presence of proteins (Ref 49, 56, 65). If the material is not potentiostatically held, then oxide disruption results in a negative excursion in potential and a much longer repassivation rate (Ref 68, 69).

Thus, the mechanism of mechanically assisted corrosion has at its core a mechanical disruption of the oxide. Therefore, mechanical factors related to oxide film stability are important. How well adhered the oxide is to the substrate; how hard the substrate is; the work-hardening behavior of the substrate, oxide, and metal modulus; the fracture strain/stress of the oxide; and the extent of residual stress in the oxide (resulting from the lattice mismatch between the oxide and the metal) are all important mechanical factors that affect the stability of the film. Some of these properties may be affected by immersion into physiological solution (Ref 70). Also, the mechanical process that may give rise to the oxide disruption is important. This can include wear (fretting or otherwise), surface deformation, or bulk deformation that causes dislocation motion up to the surface. It should be noted that the fretting resistance of titanium alloy surfaces is relatively poor compared with cobalt-chromium and stainless steel alloys. That is, it is easier to abrade the oxide of titanium than it is cobalt-chromium or stainless steel alloy surfaces (Ref 16). Thus, one factor in the use of these materials is that titanium may have a greater susceptibility to corrosion events during mechanically assisted corrosion, which is supported in the retrieval studies.

In the instant of time immediately following oxide disruption, very high rates of oxidation (corrosion) take place. Some of this oxidation goes to form new oxide film that, once reestablished, reduces the rate of oxidation until the surface oxide is reformed and returns to its resting condition. The electrochemistry that results in the instant following disruption has several aspects to it that should be understood.

First, both dissolution and film formation reactions result in the generation of free electrons (see equations, Fig. 5). Here, free electrons refer to those electrons liberated in the oxidation reactions that remain (for a time) in the metal. The film formation reaction takes oxygen from water and generates free electrons and hydrogen ions, while metal atoms oxidize to metal ions and leave electrons behind in the metal as they dissolve into solution or go to form new oxide film. Thus, both reactions create a significant excess of electrons that remain (at least for a period of time) in the metal. This has the effect of lowering (making more negative) the overall potential of the metal being corroded. Thus, if one were to monitor the potential of a metal being subjected to mechanically assisted corrosion, one would see that it would decrease (become more negative) with increasing amounts of oxide film disruption per unit time (Ref 50, 68, 69). The

Fig. 3 SEM micrographs showing corrosion attack of a 316L stainless steel modular junction (both surfaces are the same alloy) from a retrieved intramedullary rod (e.g., see Fig. 1c) and from a retrieved SROM modular total hip replacement where the body of the femoral component has a major tapered interface between two Ti-6Al-4V alloy surfaces. (a) Low-magnification SEM micrograph of cone surface of the 316L intramedullary rod showing corrosion attack. ($\sim 35\times$). (b) Higher magnification of 316L stainless steel surface showing the mechanically assisted corrosion attack at a severe stage. The surface has been etched and pitted by the body fluids such that any sign of fretting has been eliminated. (c) Low-magnification SEM of a Ti-6Al-4V/Ti-6Al-4V modular interface for a SROM modular total hip stem. The modular interface in this case is between the stem and the proximal shell, which is designed to provide a site for bony ingrowth. The interface between the stem of the in-growth pad has severe corrosion. The left side of the micrograph shows severe corrosion and the right side does not (and was outside of the crevice zone). (d) Higher magnification of the stem side of the SROM interface showing attack of the Ti-6Al-4V microstructure

Fig. 4 Plot of the open circuit potential (OCP) shift that takes place during deformation associated with the deployment of a 316L stainless steel vascular stent. The angular wire bends that make up the stent geometry are plastically deformed during deployment, which disrupts the oxide film on the surface and results in a sudden generation of electrons (from the oxidation process), which causes the OCP to drop.

extent of potential excursion depends on the rate of excess electron generation (the corrosion rates), the relative surface area abraded to the total surface area of the metal exposed to solution, the rate at which the electrons are consumed by reduction reactions (e.g., $\text{H}_2\text{O} + \frac{1}{2}\text{O}_2 + 2e^- \rightarrow 2\text{OH}^-$), and the area available for the consumption of electrons by reduction reactions.

For example, if the fraction of a titanium sample area, being subjected to mechanically assisted corrosion is a significant percentage (greater than 1%) of the total area, potential drops of about -200 to -400 mV can be observed. If the area abraded rises to 10 to 30%, the drop can be up to -600 to -800 mV, and if the entire area is abraded, potential drops of up to -1 V can be observed (Ref 68, 69).

This has implications for the subsequent corrosion behavior. For instance, with a drop in potential, the electrochemical driving force for continued corrosion and/or oxide film formation is decreased. Therefore, with abrasion, the voltage drops and the amount of film that grows and the amount of ions dissolved per unit area may be decreased as the potential gets more negative. Also, it takes a significant amount of time (e.g., several hundred seconds) for the voltage to recover after an abrasion event when reduction reactions alone are responsible for the process (Ref 71). Thus, when abrasion takes place on a small relative area, there is a small voltage drop (because the majority of the area is unabraded and therefore potential controlling), and the repassivation of the abraded area is relatively fast. When the area fraction abraded increases, there is a greater potential drop and it takes longer for the repassivation process to take place.

It should be noted that oxide film formation does not require the presence of dissolved oxygen. Hydrolysis of water is all that is needed. In fact, organic solutions with as little as 1%

water present can repassivate titanium (Ref 64, 65).

Second, sudden disruption of a surface and the electrochemical reaction that ensues can and does give rise to a transient electric field that can propagate away from the surface. This field results in an imbalance of charge at the surface, which causes a flux of ions in the solution. This effect can be sensed up to 5 to 7 mm (0.20 to 0.28 in.) away from a $50 \times 10 \mu\text{m}$ (0.4 mil) scratch imparted in 1 ms (Ref 72). There are bioelectric ramifications of this process, including nerve stimulation (e.g., pain) near the site of an abrasion.

Third, it should be noted in the preceding electrochemical reaction for repassivation (film growth) that another by-product of repassivation is the generation of hydrogen ions at the site of abrasion. These hydrogen ions may remain in the solution and result in a significant drop in the pH in the vicinity of the mechanically assisted corrosion. This is especially true if the local environment is restricted, with limited transport of fluid into and out of the crevice, as is the case in modular tapers. In these cases, the pH of the solution near the abrasion, along with the concentration of metal ions in the solution can be dramatically altered from the bulk solution (body environment). Ionic concentrations have been measured within the modular connections of total hip replacements with upward of 3 to 6 ppm of Co ions during laboratory testing of modular components (Ref 50). Measured pH within these modular tapers has been observed to be as low as 3 (Ref 73). There is other evidence that the pH in modular tapers can achieve a pH level below 1 in some cases. The evidence for this (Fig. 7) is that in some retrieved and highly corroded titanium-titanium modular components, highly corroded interfaces of Ti-6Al-4V couples retrieved have been observed where the attack started as

mechanically assisted corrosion but clearly became an electrochemical attack (evidence of fretting was corroded away), as shown in Fig. 7(a), (b), and (c). Also observed in these retrieved devices was the precipitation of titanium phosphate particles in the inner region of these modular pieces (Fig. 7d). Severe corrosion of Ti-6Al-4V of the type observed can occur only when the pH of the solution is approximately 1 or less (Ref 74). Titanium phosphate can occur in this state only if the titanium is present as ions and subsequently reacts with phosphate ions at pHs below about 1. This can be shown by placing titanium particles into an aqueous solution of phosphoric acid ($\text{pH} = 0$). A purple color will ensue over time that indicates Ti^{3+} ions were going into solution (Ref 75). With time, the hydrogen ions reacted with the titanium particle surfaces to form hydrogen gas which raised the pH. As the pH reached a level above 1, the titanium ions precipitated out as titanium phosphate particles identical to that seen in the retrieved implant case (Fig. 1d and 7).

Drops in pH and negative excursions in potential can combine to result in placing a metal surface in an active condition. That is, there are ranges of pH and potential where the oxide film is no longer stable and it will not reform once abraded. The underlying metal will still be subject to corrosion and will corrode actively under these conditions. This means that, once the conditions for active corrosion are established, mechanical abrasion is no longer a necessary condition for continued high levels of corrosion within the crevice. This has been observed to be the case in testing of modular tapers where electrochemical evidence of continued corrosion after 1 million cycles of fatigue loading

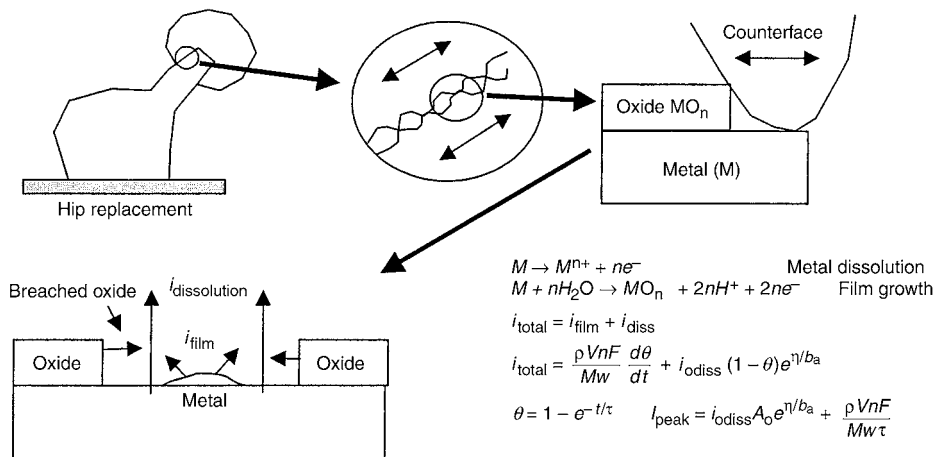

Fig. 5 Schematics across spatial scale showing aspects of mechanically assisted corrosion process for a modular connection in a total hip replacement. The contact region within the taper is rough with regions where solution can gain access. The counterfaces can slide relative to one another due to either rigid body motion or elastic deformation. Sliding with sufficient surface contact stress will cause oxide abrasion and high-current densities associated with repassivation and ionic dissolution. The total current transient then can be thought of as the sum of these two contributions. If one assumes θ to be the fraction of abraded oxide volume that has reformed at any time, and $(1 - \theta)$ to be the fraction not yet reformed, then the above differential equation can be used to model the transient response. Source: Ref 49, 52

Fig. 6 Typical current transient that results during an $80 \mu\text{m}$ scratch test with a diamond stylus (radius of $20 \mu\text{m}$, or 0.8 mil) on a Co-Cr-Mo surface in phosphate buffered saline potentiostatically held at a passivating potential (0 mV SCE) and loaded with a 1.5 GPa contact stress. The scratch requires about 1 ms to impart and the current transient rise and decay occur within about 2 to 5 ms . The scratch is not complete before the beginning of repassivation so the peak current underestimates the real bare surface current density. Based on the geometry of the scratch ($80 \times 10 \mu\text{m}^2$), the current density is ($2.5 \mu\text{A} / 800 \mu\text{m}^2 = 0.31 \text{ A/cm}^2$). Inset is another example where data are fit with an exponential equation of the form $I = 0.1 + 2.15 \text{EXP}(-(t - 0.003) / 0.0015)$. See text for details.

remained for up to 72 h after the end of loading (Ref 50) and in retrieved implants where pitting and grain-boundary attack are seen without signs of fretting (i.e., the fretting scars were corroded away) (Ref 29, 37, 39). Low pH may also promote hydrogen embrittlement of the metals; however, this has not been investigated for biomaterials.

Fourth, mechanically assisted corrosion can occur on any metal surface where an oxide is present. That is, mechanically assisted corrosion has been reported on stainless steel-stainless steel couples (intramedullary rods in vivo (Ref 37), cobalt-chromium to cobalt-chromium couples (modular head-neck junctions in total hips) (Ref 29, 32, 40), titanium alloy-titanium

alloy couples (Ref 29, 39), as well as with any combination of these alloys including cobalt-chromium to stainless steel (Ref 58) and cobalt-chromium to titanium. The necessary conditions for this to occur include sufficient mechanical factors to repeatedly disrupt oxide films, and restricted environments that can result in large changes in local chemistry.

Testing of Mechanically Assisted Corrosion

There have been several tests developed to investigate aspects of mechanically assisted corrosion. These include device tests of geome-

tries that represent modular hip connections and their loading and electrochemical environment (Ref 50–54, 58, 76). Also, high-speed scratch testing has been performed where controlled contact stresses, voltage, solution conditions, and scratch area are maintained and the current transient associated with oxide film disruption is monitored (Ref 49, 55, 56, 60–65). While there are some limitations to these tests, they are able to provide a significant amount of insight into the processes occurring.

Scratch Test. In particular, the electrochemical scratch test method (Ref 49, 55, 56) has been able to show many of the important mechanical and electrochemical factors that influence the behavior of these oxide film-covered alloys during mechanical abrasion. During scratch testing, a well-characterized stylus (diamond) is brought into contact, with a known force, with an oxide film-covered surface immersed in a physiologic solution and potentiostatically held. Then, a high-speed piezoelectric actuator applies a scratch of known length (e.g., 80 μm , or 3 mils) in 0.5 ms. The current response (Fig. 6) to this abrasion event is then measured and used to analyze the behavior. Note that the transient response appears to be an exponential decay process (i.e., $I = I_0 + I_{\text{peak}} e^{-(t-t_0)/\tau}$, where I_0 is the baseline current, I_{peak} is the peak current away from the baseline, t_0 is the time to reach the peak, and τ is the time constant for the decay). The magnitude of the current spike (above the background current level) depends on the scratch length, scratch speed, the contact load, the potential, and the solution conditions (Ref 49, 55, 57, 77).

For example, the effects of contact stress and potential on the scratch behavior of cobalt-chromium is summarized in Fig. 8. These plots show how the peak current in the transient varies with applied load at a fixed potential (Fig. 8a) and how the peak current varies with applied potential at a fixed load (Fig. 8b). From Fig. 8(a), it can be seen that the load (and therefore the contact stress) to cause oxide film disruption is about 0.05 N (or about 1 GPa) (Ref 49, 55, 56) and that below this load, no current transient is observed. Increases in the peak transient with load above this level indicates greater amount of oxide area abraded with the higher loads due to the load dependence of the contact area. These observations are consistent with Hertzian contact stress analysis, where the area of contact varies with load. Figure 8(b) shows how the peak current varies with potential during a scratch test in a phosphate buffered saline. Here, one can see that below approximately -500 mV vs. SCE (i.e., the passivating potential, E_{pp}), there is no measurable current transient, while above this voltage up to about $+500$ mV (i.e., the breakdown potential, E_b), the peak current increases with potential. Above $+500$ mV SCE, the peak current drops as the material enters the transpassive region and the oxide film is no longer as good a barrier to corrosion. Thus, this plot clearly demonstrates the potential range wherein the oxide film reforms after mechanical disruption.

Fig. 7 SEM micrographs of Ti-6Al-4V/Ti-6Al-4V modular connections for a total hip replacement device from a retrieved device (due to ceramic head fracture). This modular connection consisted of a femoral neck taper onto which was placed a Ti-6Al-4V "thimble" to allow a ceramic head to attach to a titanium stem (see Fig. 1d). (a) Optical micrograph of cross section of thimble-neck taper junction intact. (b) SEM micrograph of the interface in (a) showing the Ti-6Al-4V microstructures for both sides of the interface and the gap between the two filled with corrosion debris. Note that there is an approximate 50 μm (2 mils) gap between the two sides and apparent corrosion attack at the grain boundaries of the titanium microstructure. (c) SEM micrograph of the neck surface in the junction region after separation of the interface. Note the penetrating corrosion attack of the grains in this micrograph. (d) Backscattered electron micrograph of the thimble portion of the device (Fig. 1d) showing the corrosion debris accumulation in this region. (e) Backscattered electron micrograph of Ti-phosphate precipitates within the thimble region (near the hole at the proximal most part of the device). These Ti-phosphate particles are indicative of a very low pH condition within these taper environments (below 1).

Below -500 mV, no oxide reforms (or there is no oxide film present due to reduction of the oxide), and above $+500$ mV, the Cr_2O_3 -rich film is no longer thermodynamically stable as the Cr increases its valence from $+3$ to $+6$. These observations have been confirmed by electrochemical atomic force microscopy (AFM) tests of cobalt-chromium-molybdenum and direct observation of the film formation process at this voltage (Ref 78–81). The time constants for repassivation are also dependent on potential (Fig. 8c). Here, as the potential falls below -500 mV, the time constant drops to zero, and above $+500$ mV it rises rapidly as the oxide becomes transpassive.

Scratch testing, therefore, is a highly systematic and sensitive means for assessing the details of the mechanically assisted corrosion process where mechanical, electrical, and chemical aspects of the corrosion process can be evaluated. There are some limitations to the

scratch test. Primarily, the rate of scratching may not be high enough to fully abrade the surface before some repassivation takes place. Thus, peak current densities may be underestimated by this technique.

In Vitro Fretting Corrosion Test. Another testing method used to evaluate medical devices, specifically modular connections, is the in vitro fretting corrosion test method (Ref 50–54). In these tests, the sample where the fretting occurs (i.e., the taper region, see Fig. 9) is separated spatially from the rest of the component. An ammeter is placed between the two portions and a voltmeter with a reference electrode is used to monitor the overall potential of the test system during fretting crevice corrosion testing. The sample is then immersed in saline and testing is begun by applying cyclic mechanical loads to the head of the device and monitoring the electrochemical response. When fretting begins, one can observe a current waveform that is in phase

with the loading cycle (Fig. 10a, b, c). One can use this test setup to evaluate materials and design variations, as well as test specific effects of the solution on the performance of these tapers.

One such test is where the cyclic load magnitude is incrementally increased and the increase in current and decrease in potential can be monitored (Fig. 10b and c, respectively). By monitoring the current and potential changes, the mechanical conditions whereby fretting crevice corrosion starts can be determined. Also, long-term cyclic tests can be performed with periodic sampling of current and potential (Ref 50). These measurements (along with post-test optical and SEM analysis of the taper surfaces, and particle and ion analysis of the solution) can provide detailed understanding of the long-term behavior of these taper systems. This approach is also easily adapted to the study of other medical devices that contain metal-metal contact points that are potentially susceptible to mechanically assisted corrosion. Testing of other devices, including spinal constructs, vascular stents, bearing surfaces, and so forth, are all possible with this test methodology.

Summary

Oxide film covered alloy systems used in medical applications are all susceptible to increased corrosion when mechanical aspects are incorporated into the overall behavior of the

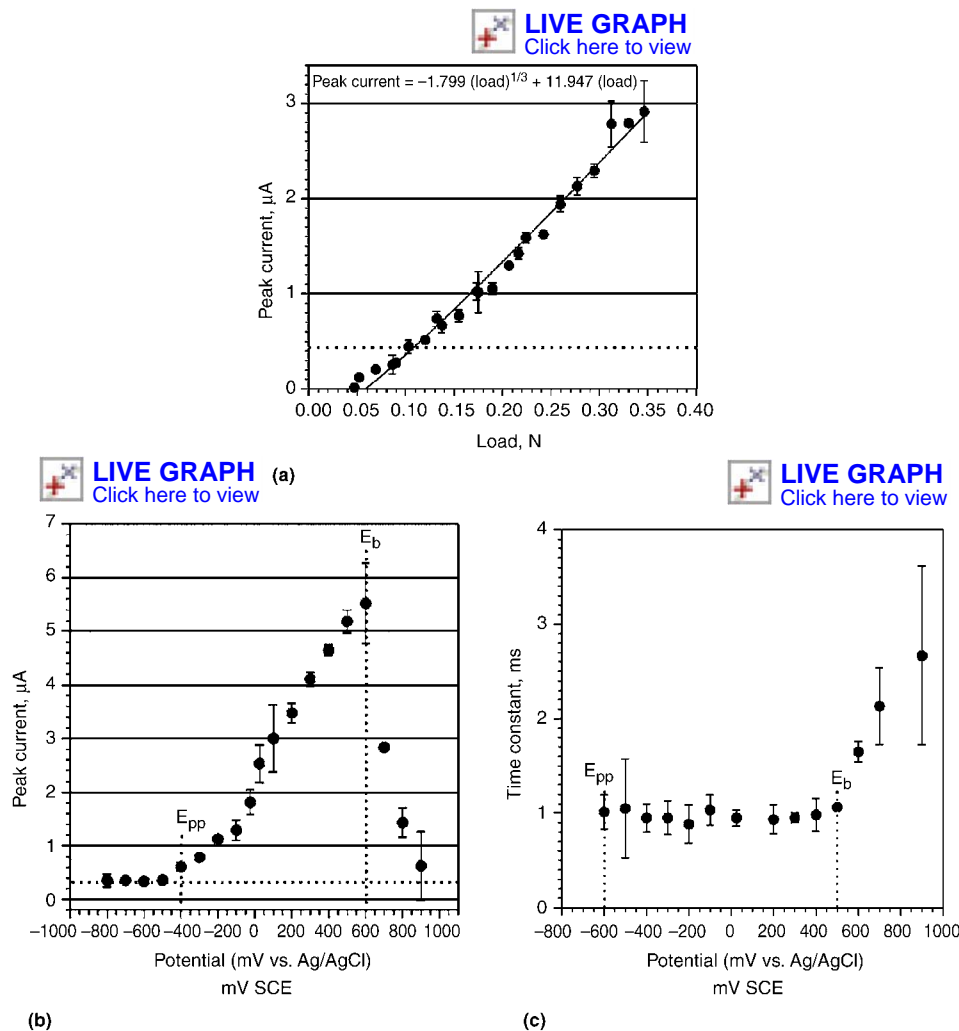

Fig. 8 Summary of scratch test for Co-Cr-Mo alloy surface demonstrating how the oxide electrochemically reacts to disruption while under potentiostatic control. (a) Peak current variation with contact load (or contact stress). (b) Peak current as a function of applied potential at a fixed contact load and scratch length. (c) The time constants for recovery as a function of applied potential. Note that the response depends on the applied load with a lower limit load indicating where the oxide does not disrupt. The potential effects on peak current and time constants show the range of potentials where the oxide film is stable and where it either does not reform (at low potentials) or has lost its passivity (at high potentials). Note that the time constants increase significantly at transpassive potentials (above about 500 mV).

Fig. 9 Schematic of modular taper fretting corrosion test setup used to evaluate the susceptibility of total hip replacement designs to mechanically assisted corrosion. Monitoring of OCP of the test setup and current passed between the working electrode and a second electrode meant to represent the remaining stem portion allows for quantitative assessment of the conditions needed to cause fretting crevice corrosion. Also, solution ion levels, particulate levels, and pH can be monitored in this test during and after either short-term and/or long-term cyclic loading.

device. Because most metallic medical devices are used specifically to withstand the mechanical environment, the corrosion behavior of these materials cannot be separated easily from their mechanical behavior. Little is known at present about the mechanical behavior of nanometer thick films in aqueous environments. However, it is clear that there is a significant probability for oxides to have variable mechanical properties, including adhesive strength, modulus, fracture strain, and so forth when exposed to potentials and solution conditions at the surface of the metal alloy. Also, the high electric field conditions of the oxide in solution can affect the adsorption of proteins to the surface and segregation of metal atoms and ions near the surface. Much is yet to be understood about metallic surface oxides in physiological solutions and the advent of the electrochemical AFM is providing a significant new capability (Ref 78–81) to understand and study these films in situ.

From this analysis of mechanically assisted corrosion of implant alloys, there are several factors that should be considered in the design and use of these materials. When crevices are expected that will experience significant cyclic loading, care must be taken to minimize one of several aspects of this overall process. One can design out the possibility of mechanically assisted corrosion by either eliminating the crevice altogether (eliminate modularity), minimize the ability of fluid to ingress into the crevice site, or, if this is not possible, design the crevice geometry to allow for fluid recycling so that low pH, high ion conditions do not develop. Surface

treatments that harden the surface and prevent oxide disruption may also provide some benefit. However, these approaches need to be taken with caution as the typically hard materials that make up these coatings (physical vapor deposition or chemical vapor deposition type coatings, or ion implantation, for example), may abrade themselves with time and result in an aggravated condition for continued wear. Designs that minimize the potential for fretting motion (either by elastic deformation or rigid body motion) also should be considered.

It is clear that metallic biomaterials will continue to be used in medical devices for the foreseeable future and that the mechanical and electrochemical performance of these surfaces will be an important part of the success or failure of these materials and the devices they comprise. The complex, interdependent nature of mechanically assisted corrosion mechanisms is evident in this article. Understanding of these processes requires in-depth knowledge of surface contact mechanics, surface structure and chemistry, electrical phenomena, and corrosion behavior. The biological context and how it may affect these processes is also very poorly understood. Most tests have not included the complexity and local heterogeneity that may arise when a metal is implanted into a living system (inflammation, proteins, enzymes, cells, etc.), which may affect the overall process in vivo. Much is still to be learned about how these biological species and processes interact with the highly energetic surfaces of metallic biomaterials.

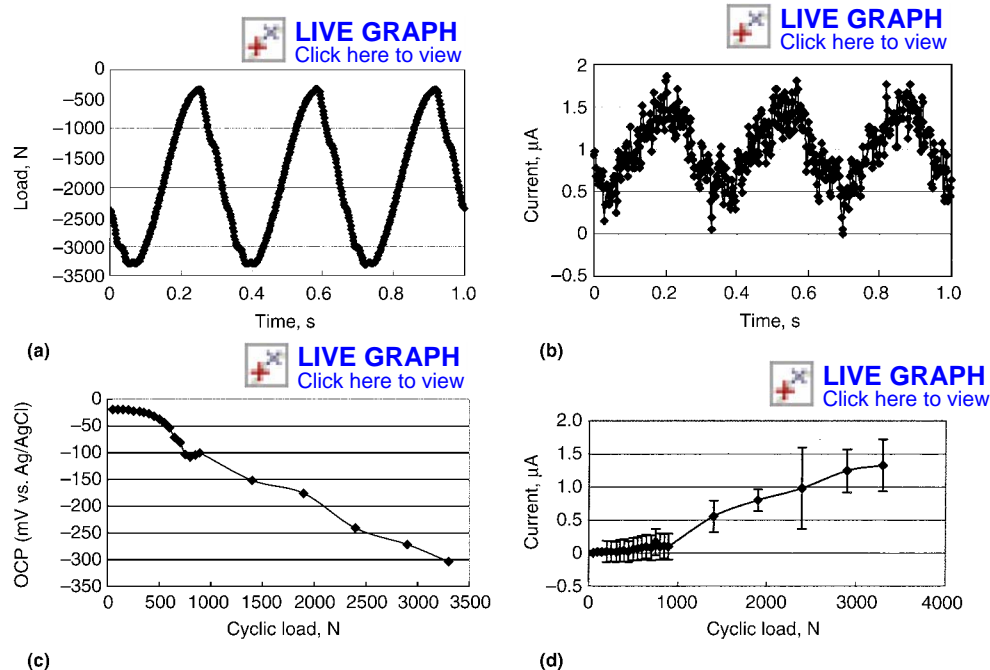

Fig. 10 Summary of results of one of the mechanically assisted corrosion tests of a modular femoral hip taper interface. (a) Load vs. time showing a compressive cyclic load to 3300 N applied at 3 Hz. (b) The corresponding fretting current measured between the working and second electrodes (see Fig. 9). Note that the current is correlated with the loading. (c) Summary of the OCP vs. applied cyclic load. (d) Mean current (and rms current—error bars) vs. applied cyclic load. Note that there is a load at onset where fretting corrosion can be detected (~500 N) in both the currents and potential shifts observed. Also, note the increased corrosion currents measured with increasing load and the larger drop in OCP indicating increased corrosion reactions.

ACKNOWLEDGMENTS

I would like to acknowledge several of my students who contributed to this work: Christine Buckley, Jay Goldberg, Saryn Goldberg, and Spiro Megremis. Also, discussions with Dr. Zhijun Bai were particularly helpful in the preparation of this manuscript.

Corrosion Performance of Stainless Steels, Cobalt, and Titanium Alloys in Biomedical Applications

Zhijun Bai and Jeremy L. Gilbert, Syracuse University

BIOMATERIALS used in medical devices and prostheses are implanted into the human body to replace, repair, or restore the function of tissue. The term *biomaterial* includes synthetic materials such as metals (alloys), polymers, and ceramics as well as some natural materials including bioceramics (e.g., hydroxyapatite) and biopolymers (e.g., collagen). Metallic biomaterials represent the most highly used class of biomaterials and generally have advantages over other biomaterials in terms of mechanical properties, such as high tensile strength, high fatigue strength, and good processability.

Biomedical devices are usually subjected to static or dynamic forces, such as in orthopedic and cardiovascular applications. For example, various artificial joint implants, fracture fixation devices, heart valves, and vascular stents are all subjected to significant repetitive loadings. On the other hand, some electrode materials, such as pacemaker leads, are made of metals such as

cobalt-base alloy (MP35N) or platinum alloy (Pt-Ir) because of their good electrical conductivity and because they are not as highly stressed. Dental alloys are another group of metallic biomaterials that include noble alloys and base metal alloys (including nickel- and cobalt-base alloys), but the details of these alloys are discussed elsewhere (see, for example, the article “Corrosion and Tarnish of Dental Alloys” in this Volume).

The history of the use of man-made materials in a human body can be traced back thousands of years. The development of metallic biomaterials was discussed in previous publications (Ref 1, 2). The main metallic biomaterials in use today can be categorized into three groups: iron-base alloys (stainless steels), cobalt-base alloys, and titanium-base alloys. While other metals and alloys are used, this article focuses only on the corrosion behavior of these three groups. These alloys all form a thin, compact, semiconducting oxide

(or hydroxide) film (usually called a passive film) that protects the substrate alloy from corrosive environments as well as interacts with the host during the host response. To understand corrosion requires an understanding of these oxides.

Chemical Composition and Microstructure of Iron-, Cobalt-, and Titanium-Base Alloys

The chemical compositions of the most commonly used metallic biomaterials made of stainless steels, cobalt alloys, and titanium alloys are given in Tables 1 to 3. Typical microstructures for these three major alloy systems are shown in Fig. 1.

Stainless steel, in the form of 316L stainless steel (Ref 3), is a widely used material for

orthopedic applications (particularly for fracture fixation and spinal devices) and cardiovascular applications (e.g., stents) because of its competitive cost, wide availability, and mechanical

properties. The main constituents of stainless steel are iron, chromium, nickel, and carbon. Addition of other elements such as molybdenum, manganese, and nitrogen improves either their

corrosion properties or their mechanical properties or both. Chromium is the most important alloying element and is the major constituent that forms the passive chromium oxide film to protect the surface from corrosion. One of the requirements for stainless steels in medical applications, from a microstructural perspective, is that the material must have a single austenitic phase with face-centered cubic (fcc) structure and be nonferromagnetic. These characteristics are very important for corrosion resistance, mechanical behavior and safety considerations. Chromium is a ferrite stabilizer (body-centered cubic, or bcc, structure), so its content in stainless steel is usually below 24% but must be higher than 12% to form a continuous passive oxide film on the surface to provide corrosion resistance. Similarly, molybdenum is another ferrite stabilizer that is added to also enhance localized pitting corrosion resistance. Its content cannot exceed 3%. Nickel is included because it is not only an austenite stabilizer but also improves the processability of the alloy. However, there are concerns with nickel because, when corroded, it forms a potentially toxic ion that may induce metal allergy in some patients. It is replaced by manganese in newly developed stainless steels such as F2229 (Ref 4). Carbon serves as an interstitial strengthening element, but its content must be limited to 0.08% or less; otherwise, it may precipitate metal carbides through a process known as sensitization (Ref 1) and could lower the corrosion resistance of the alloy. In fact, for the main stainless steel used, 316L stainless steel, the “L” stands for low carbon (0.03 wt%). More recently, nitrogen was alloyed to enhance the mechanical and corrosion properties of iron-base alloys, and the corrosion resistance of these newer stainless steels looks very promising. Phosphorus and sulfur are inclusion elements whose content must be controlled; otherwise, they will cause deleterious effects on the corrosion resistance by preferential dissolution of the inclusions (Ref 5). Another requirement for stainless steel is a fine grain microstructure that is crucial for strength and fatigue properties.

Cobalt-base alloys come in a variety of compositions that can include cobalt, chromium, molybdenum, nickel, tungsten, and other elements (Ref 6–10) and have a highly complex microstructure. Chromium is the main corrosion-resistant element, forming chromium oxide as a

passive-film kinetic barrier, while molybdenum is another main constituent added to improve the pitting corrosion resistance and the mechanical properties. The mechanical properties of cobalt-base alloys are critical to their performance. These alloys typically have a fcc or hexagonal close-packed (hcp) crystal structure, depending on the thermomechanical processing, and have high strength and high work-hardening coefficients due to their low stacking fault energy and planar slip characteristics. These alloys are also comprised of complex carbides that are typically dispersed in the microstructure. Alloying with refractory elements (molybdenum or tungsten) and forming carbides will increase its strength. Various thermomechanical processing methods, such as wrought or forging processes, are used to improve the strength and fatigue resistance. These alloys are also highly wear resistant and are typically used in wear applications, such as the head of a total hip replacement.

Titanium and its alloys (Ref 11–16) are also very high-strength materials with relatively low moduli that typically contain hcp and/or bcc crystal structures and have very high corrosion resistance, relying on the formation of a titanium dioxide (TiO_2) film. The mechanical properties of titanium mainly depend on its microstructure and its solid-solution strength, which is related to composition and heat treatment. Pure titanium has a single hcp crystal structure with lower strength. Elements of vanadium, niobium, and chromium are beta-phase (bcc) stabilizers, while aluminum, oxygen, and zirconium are alpha stabilizers. Alloying with these elements can improve the strength and fatigue resistance. Another titanium alloy that is seeing increased use is nickel-titanium (NiTi) alloy (Ref 17). This near equiatomic alloy has superelastic and shape memory characteristics and is used in cardiovascular applications.

Surface Oxide Morphology and Chemistry

Upon insertion into the human body, biomedical devices will experience a series of interactions between the biomaterial and the host, and

corrosion is part of this interaction. Therefore, the structure, chemistry, and behavior at the surface of biomaterials is critical in determining the biocompatibility. This section discusses the surface morphology and chemistry of these oxide-film-covered alloys and provides insight into the interaction.

There are a number of surface analytical methods that can be used to evaluate the surface chemistry and surface morphology of passive-film-covered biomaterials surfaces (Ref 18). Among them, atomic force microscopy (AFM) and x-ray photoelectron spectroscopy (XPS) are two powerful approaches. Atomic force microscopy can provide surface morphology information at the micron to nano level in air or in solution and can be combined with electrochemical polarization testing. X-ray photoelectron spectroscopy can investigate the surface chemistry of the thin oxide films at the nano level with very high accuracy. Furthermore, XPS can be used to study the chemical valence state and depth distribution of elements in the film.

Typical three-dimensional AFM images of stainless steel, Co-Cr-Mo, commercially pure titanium (CP-Ti), and NiTi alloy are given in Fig. 2. The images show that each of these surfaces is covered by a domelike oxide film, even in the grain-boundary region or overtop of some inclusions (not shown). The size (diameter and height) of oxide domes on these alloys is a function of immersion time, electrochemical history (potential and pH), and prior surface treatment (Ref 19–22). Specifically, titanium oxide domes will spread laterally and flatten out with increasing applied potential. From in situ electrochemical AFM, Co-Cr oxides appear to form at approximately -500 mV versus saturated calomel electrode (SCE) and grow over the potential range between -500 mV and approximately 250 to 300 mV, where significant changes begin to occur. By 400 to 500 mV, the oxide film on Co-Cr alloys begins to break down, before the transpassive potential of the alloy, indicating that oxide film structural changes precede current rises associated with breakdown.

From XPS results (see subsequent information), it has been shown that the surface chem-

istry of oxides on Co-Cr and stainless steel alloys is chromium rich, while the titanium and NiTi alloys are predominantly titanium oxide surfaces. Another aspect of these oxide films is that the measured height of oxide domes appears higher than 10 nm, except for Co-Cr-Mo, which is closer to 10 nm, based on AFM measurements. This is at odds with XPS depth measurements (argon ion sputtering), which show these oxide domes to be in the 1 to 5 nm range.

Table 4 reviews the surface chemistry for passive films formed on these metallic biomaterials. It can be found that all passive films have film thicknesses ranked as several nanometers and that they are significantly affected by chemical or electrochemical surface treatments. In fact, surface oxide films (particularly their chemistry) are influenced by prior treatment. It should be noted that changes of surface morphology and surface chemistry will occur due to immersion time or potentials in the biological environment, either in vitro or in vivo, and these effects are discussed in the later sections.

Generally, the surface film of stainless steel consists mainly of chromium and iron oxides. Nickel exists in the oxide in a metallic state or nickel oxide, but severely depleted. The existence of molybdenum in the oxide is questionable, even though it plays a crucial role for preventing localized corrosion. Chemical passivation and electrochemical polishing increase the content of chromium, enhance the ratio of chromium to iron, and improve the corrosion resistance.

The surface oxide for Co-Cr-Mo alloys formed in air is primarily Cr_2O_3 with minor amounts of cobalt and molybdenum oxides (Ref 25, 27, 30). The ratio of chromium to cobalt is varied in different media, such as lab air or wet steam (Ref 25), and is influenced by various surface treatments, such as passivation in nitric acid (Ref 27).

The dominant chemical species for surface films on titanium and its alloy is TiO_2 with, perhaps, lower-valence oxides such as TiO and Ti_2O_3 present, particularly in the inner layer. For the Ti-6Al-4V alloy, Al_2O_3 is found in the oxide layer, while the presence of vanadium in the oxide is unclear. Shape memory NiTi alloy has a

Megremis; Ti-6Al-4V images courtesy of J. Bearinger

higher content of nickel in the alloy; however, TiO_2 is the primary chemical species in this oxide film. The chemistry of this oxide film is significantly influenced by various factors, such as prior surface treatment, fabrication methods, and heat treatments. In some cases, metallic nickel and its oxide may play a major role in oxide film behavior, and this will significantly affect its corrosion behavior.

Physiological Environment

In orthopedic and cardiovascular applications, biomedical devices are in contact with human tissue. The former will be in contact with interstitial fluid, and the latter will be in contact with blood. In addition, the act of implantation results in a wound site, and therefore, all biomaterials first encounter blood and the wound-healing environment. The acute and chronic healing environment can and does significantly modify the physiological solution in important ways that may affect the surface behavior of these alloys. Ionic species, superoxide radicals and their byproducts, enzymes, pH, cell types, and a host of other factors can vary over time at the site of the alloy.

Generally, physiological electrolyte fluid is composed of various salts (mainly chloride and bicarbonate anions, and sodium and potassium cations) and various organic and biological species (proteins, enzymes, and cells). It should be noted that some special chemicals, such as superoxide radicals and their by-products

during inflammatory reactions, will be synthesized during pathological and/or wound-healing processes, and these species may play an important role in the corrosion behavior of biomaterials.

In the biological system, the pH is modulated by phosphate and carbonate buffering and is kept in the range of 7.4 under normal conditions. However, pH may vary in the wound-healing process after surgery from 5.5 to 9.0 with infection. In the case of a hematoma, the pH can become 5.5 for several days or longer (Ref 31). In some local sites, where corrosion, such as crevice corrosion, is occurring, the pH may drop to approximately pH 1 or lower (Ref 32, 33).

As for electrochemical potentials in the body, there is no general agreement for the range of values possible. The potential is likely to be material- and environment-dependent. Although bioelectric signals are continuously present in the living system, these electrical transients are usually not thought to have significant effects on the corrosion behavior of biomaterials. However, there are studies that do show some effects (Ref 34). Based on the local oxygen or hydrogen partial pressure, it has been proposed that tissues that are perfused with arterial blood have equilibrium potentials in the range of 0.782 V (versus normal hydrogen electrode, NHE) (Ref 35). However, the actual surface potential will be governed by the mixed potential theory (Ref 36), where the sum of all anodic and cathodic currents acting on the surface balance out. Therefore, the actual potential will depend on factors such as

the exchange current density for the governing cathodic (reduction) reaction, as well as the ability of the anodic processes to take place. Other factors that may affect the surface potential of these alloys include the concentration of oxidizing species (such as H_2O_2 and others) at the surface and the mechanical abrasion of the surface film. Based on the in vitro and in vivo immersion testing results, it has been asserted (Ref 37) that potentials in vivo may be approximately 0.5 V (NHE). On the other hand, abrasion of film will cause potential drops as large as -1 V (versus silver-silver chloride electrode, Ag/AgCl) for titanium oxide (Ref 38).

It seems likely that metal implant potentials in vivo are not likely to rise to above 1 V (SCE), which corresponds to the oxygen evolution potential at a normal pH value. Furthermore, as is discussed later, above 0.5 V (SCE), chromium oxide will undergo the transpassive dissolution reaction (Cr^{3+} becomes Cr^{6+}), and it will dissolve rapidly into solution. So, the reasonable range of potentials attainable in vivo is between -1 to 0.5 V (SCE). If there is an inflammatory response, those cells can produce hydrogen peroxide, and the potential may be increased to a higher value (Ref 39).

Another aspect for body solution chemistry is the content of dissolved gases. There are some differences between body fluid and lab conditions, particularly in the oxygen and carbon dioxide pressure in terms of low oxygen and higher carbon dioxide. These differences may have effects on the corrosion behavior of biomaterials in vivo (Ref 40).

Interfacial Interactions Between Blood and Biomaterials

Generally, upon immersion of a metal into solution, an interfacial structure is established that involves ions, water (solvent), and electrons (Ref 41). This interfacial structure, known as the electrical double layer, is complicated and far from fully understood, particularly in the case of biomaterial surfaces where semiconductor-like oxide films make contact with protein-containing ionic solutions. Thus, the interfacial structure is highly complex, and the processes that occur at the surface are similarly complex. A schematic representation of an oxide-film-covered surface is shown in Fig. 3. Many aspects of this surface remain poorly understood. It is known that the oxide film is under a high electric field, on the order of 10^7 V/cm. Also, oxide films can transport both ions and charge (electrons and holes), are defected nanocrystalline materials with some habit relationship to the substrate, and are variable in chemistry, residual stress, and other factors that impact their behavior.

Within seconds or minutes of insertion into a body, the biomaterials will be subjected to the adsorption of blood proteins. Albumin is the first protein adsorbed on the surface, but it will be replaced by other proteins regulated by the Vroman effect (Ref 42). Fibrinogen may be adsorbed on the surface in its highest concentration, and it may be partially replaced by other high-molecular-weight proteins, such as von Willebrand factor. Protein adsorption plays a central role in the physiologic consequences of biomaterial implantation, including coagulation, thrombogenesis, and acute and chronic inflammatory responses. In addition, various cells may attach to the surface of biomaterials in either orthopedic or cardiovascular applications (Ref 43–45).

Coagulation and Thrombogenesis

Artificial surfaces may induce thrombosis (or blood clot formation), and the controlling mechanism for this has not been completely

determined. Protein adsorption, in particular, fibrinogen adsorption, is thought to play a central role in thrombosis (Ref 46). There are two pathways thought to initiate fibrinogen-fibrin conversion (intrinsic and extrinsic coagulation) (Ref 47). Fibrin will form a network and trap blood cells, thus forming a thrombus. Numerous papers have been published on protein adsorption on artificial surfaces; however, most of them focus on polymer surfaces (Ref 48, 49) and relatively fewer on metal or oxide films (Ref 50). The mechanism and controlling factors of protein adsorption are still unclear (Ref 48). Researchers believed that thrombogenesis is electrochemical in nature (Ref 51–53) and that electrochemical potential (charge) governs the thrombogenic properties of metallic biomaterials (Ref 54, 55). That is, the material that has an open circuit potential more negative than 0 V (NHE) was seen to be nonthrombogenic, while more positive potentials resulted in thrombogenic effects. Studies (Ref 56) show that potential can cause fibrin conversion from fibrinogen on the surface of platinum without enzymes. Reference 57 asserted that the semiconductivity of oxide films influences the thrombogenicity of artificial materials in terms of band energy and surface states.

Inflammatory Response to Biomaterials

Recent research (Ref 58, 59) reviewed the biological responses to materials and found that there is a sequence of host reactions following implantation of medical devices, including the metallic biomedical devices. Usually, the implantation of biomedical devices will cause injury and lead to the subsequent cellular cascades, including inflammation and foreign body reactions, that usually occur within two to three weeks after implantation.

Macrophages play a central role in the acute and chronic inflammatory processes, because phagocytosing (ingesting) macrophages will undergo respiratory burst reactions that release H_2O_2 and other superoxides such as NO. These species may have large effects on the corrosion of biomaterials (e.g., shifting potentials to a more anodic range) (Ref 60).

General Discussion of Corrosion Behavior of Three Groups of Metallic Biomaterials

There are several special aspects of corrosion of biomaterials that are different from corrosion in industrial practice. First, the primary concern for biomedical devices is the host reaction to the corrosion products (biocompatibility) as well as the damage to the device itself. Second, as discussed before, the metal surface is always covered by a layer of proteins or cells that modulate biomaterials-host reactions, including corrosion. Third, in some applications, for example, vas-

cular applications, the interaction between the metal surface and proteins or cells is very important in terms of biocompatibility. Fourth, although the in vivo environment is dynamic in localized sites, it is a relatively isolated stagnant aqueous solution with limited volume. The hydrolysis constant and solubility of corrosion product in solution may play a vital role for their corrosion behavior. Furthermore, various elements (e.g., nickel, chromium, etc.) are not well tolerated by tissue, with adverse reactions, including allergic and inflammatory reaction, possible.

Electrochemical Reactions. Metallic corrosion is an electrochemical reaction in nature; that is, metal oxidizes in an anodic reaction to a higher valence state and forms ions or hydroxide (oxide) while also giving up electrons. These generated electrons are consumed by other cathodic (reduction) reactions at different sites. Reduction reactions include reduction of dissolved oxygen, hydrogen, or other reactions. Typical oxidation reactions for a metal are listed as follows (Ref 61).

Anodic dissolution resulting in a soluble cation:

This reaction is suitable to almost all alloy components of metallic biomaterials in vivo conditions, particularly for iron, cobalt, nickel, vanadium, and molybdenum.

Passivation and formation of insoluble oxide or hydroxide:

This passivation reaction occurs for elements such as chromium and titanium in biomaterials.

Forming an insoluble oxide product:

Furthermore, there may be other anodic (oxidation) reactions for biomaterials (e.g., involving chromium) (Ref 62). For example, see Eq 4 and 5.

Passivation by forming an insoluble product from a dissolving surface:

Transpassive dissolution of a passive surface:

Typical cathodic reduction reactions include:

Fig. 3 Schematic diagram of the interfacial structure of a biomaterial surface contacting with the biological environment

In some local areas (e.g., crevice site), the dissolving metal cation may induce hydrolysis:

Metal oxidation may produce metal ions (Eq 1), and these ions can migrate away from the metal surface as free ions in solution or form metal oxide (hydroxide) or other chemical compounds with other species. From a thermodynamic point of view, the oxidation of metallic biomaterials is a spontaneous (exothermic) process, because metal ions or oxides are more thermodynamically stable than the metal. The corrosion of metallic biomaterials in body fluids is controlled by thermodynamic and kinetic factors: the former determines the corrosion tendencies, while the latter determines the corrosion rate.

Pourbaix proposed potential-pH diagrams (Pourbaix diagram) to describe the thermodynamics of the electrochemistry of metals or alloys in aqueous solutions (Ref 63, 64). In Pourbaix diagrams, the electrochemical behavior of metals can be divided into three domains: immunity, passivation, and corrosion. In the immune domain, the metal keeps its metallic surface because the corrosion reaction is not thermodynamically possible. In other words, corrosion will only happen at higher potential conditions, for example, Pt/Pt¹⁺ at 1.2 V (SCE). Noble metals such as gold, platinum, and silver belong to this group. In the passive domain, metals or alloys react to form oxides (or hydroxide). In some cases, these oxides will form protective surface oxides that prevent contact between the substrate alloy and the solution. Metals such as titanium, tantalum, chromium, niobium, and zirconium and their alloys belong to this group (many of which are being investigated as potential biomaterials). In fact, as mentioned before, the three main metallic biomaterials being discussed here belong to this group and mainly depend on titanium and chromium to form the passive film to prevent corrosion. It should be noted that the metals in this group are very active (i.e., they have high thermodynamic driving forces for continued oxidation) and tend to corrode rapidly in body fluids when the passive film is not present or disrupted, as in the case of severe abrasion conditions. In Pourbaix's third domain, the corrosion domain, metals will corrode and dissolve into solution and will not form protective oxide films, but rather ionic corrosion products.

For stainless steel, Co-Cr-Mo, and titanium and its alloys, the kinetic factor that controls the corrosion rate for biomaterials in aqueous solution is the passive film. Passive films play dual roles in limiting both the anodic and cathodic reactions. That is, the film serves as a physical barrier for both cation transport and anion transport to the metal surface as well as an electronic barrier for electrons.

Electrochemical Methods for Studying Metallic Biomaterials Corrosion. Various

approaches used to investigate corrosion include weight loss, visual investigation, and electrochemical methods. Electrochemical methods are extremely sensitive techniques to measure the corrosion of biomaterials, although some nonelectrochemical methods such as chemical analysis of corrosion products also are used to study the corrosion of biomaterials.

The most common way to study corrosion of metallic biomaterials is by anodic polarization (Ref 65) and electrochemical impedance measurements (Ref 66). The three-electrode system is used in electrochemical corrosion testing, that is, working electrode (biomaterial specimen), counterelectrode (inert electrode, usually platinum or carbon), and reference electrode (SCE and Ag/AgCl are the typically used reference electrodes). A potentiostat or galvanostat is used to control voltage or current and to record current or voltage, respectively. These procedures are now normally controlled by computers.

Potentiodynamic and potentiostatic methods are used to study the localized corrosion behavior of biomaterials in physiologically representative solutions, that is, controlling the electrode potentials as well as measuring the generated current response. There are several ASTM International standard test methods for localized corrosion testing, and some are particular for implant materials.

Five ASTM standards are concerned with localized corrosion and mechanically assisted corrosion of surgical implant materials. Two methods for localized corrosion properties include:

- ASTM F 746 (Ref 67), "Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials"
- ASTM F 2129 (Ref 68), "Test Method for Conducting Cyclic Potentiodynamic Polar-

ization Measurements to Determine the Corrosion Susceptibility of Small Implant Devices"

Three methods for mechanically assisted corrosion properties include:

- ASTM F 897 (Ref 69), "Test Method for Measuring Fretting Corrosion of Osteosynthesis Plates and Screws"
- ASTM F 1801 (Ref 70), "Standard Practice for Corrosion Fatigue Testing of Metallic Implant Materials"
- ASTM F 1875 (Ref 71), "Standard Practice for Fretting Corrosion Testing of Modular Implant Interfaces: Hip, Femoral Head-Bore, and Cone Taper Interface"

In addition, ASTM G 61 (Ref 72) (cyclic polarization testing) is more generally designed for screening variations in alloy composition and environments, particularly for iron- or nickel-base alloys in chloride solutions. It is used to determine the relative susceptibility of materials to localized corrosion and has been widely used in biomaterials research. In fact, ASTM F 2129 is a modification of G 61, and it uses a similar protocol to study the localized corrosion property (pitting) for biomaterials but emphasizes testing of small medical devices in simulated solutions. In these two methods, a cyclic polarization scan is carried out from active (negative) potential (usually below the corrosion potential) to a noble (positive) potential and, at some point, scanning back to the starting point, all at a fixed scanning rate. Typical potentiodynamic corrosion curves for 316L stainless steel, Co-Cr-Mo, MP35N, CP-Ti, Ti-6Al-4V, and NiTi in simulated solution are shown in Fig. 4. Typically, at the most cathodic, potentials, the current is net cathodic, indicating that the sum of all anodic and cathodic processes has more cathodic reactions than anodic ones. Then, as the potential is

Fig. 4 Typical cyclic polarization curves of stainless steel, cobalt-base alloys, and titanium alloys in phosphate-buffered saline (room temperature; scan rate, 1 m V/s; preimmersion, 10 min). (a) 316L stainless steel. (b) NiTi. (c) Co-Cr-Mo. (d) MP35N. (e) Ti-6Al-4V. (f) CP-Ti

increased, the current goes to zero, which is referred to as the corrosion potential (open circuit potential, or OCP, or zero current potential). This potential is where the sum of all anodic and cathodic reactions sum to zero. It should be noted that this potential is sensitive to prior electrochemical history. For instance, if the sample is held at a cathodic potential (e.g., -1 V versus Ag/AgCl) for a period of time, then the OCP will be shifted to more negative potentials than would be measured at rest. This result is from the fact that this cathodic conditioning alters the surface and modifies the local solution chemistry near the surface, causing a negative voltage shift in OCP.

Three other potentials of interest may be found with cyclic polarization curves. First is the primary passivating potential (E_{pp} , also named Flade potential), above which oxide film can form. This potential is often hidden in polarization curves by overwhelming cathodic reactions or is outside the range of potentials tested. Second is the potential at which the current increases significantly with increasing potential, called the transpassive potential (and also sometimes erroneously referred to as the pitting potential, E_p , or the breakdown potential for materials that exhibit pitting). The more noble this transpassive potential, the less susceptible the material is to loss of passivity or localized film breakdown (e.g., pitting attack). The third potential is called the protection potential (E_{prot}) or repassivation potential at which the reversed scanning part of the cyclic polarization curve intersects with the anodic portion of the forward scan, and a hysteresis loop is completed. It is generally accepted that if pitting occurs, the pits will propagate at potentials that are more positive than the protection potential, but repassivation will occur at potentials more negative than this point. Materials that do not exhibit this hysteresis curve are not thought to be susceptible to pitting, but they may experience a generalized breakdown of the oxide film. The Co-Cr-Mo alloys show this behavior. In Fig. 4, 316L stainless steel shows evidence of a hysteresis loop and has the lowest pitting potential, approximately 300 mV (Ag/AgCl), while Co-Cr-Mo (as well as MP35N) exhibits film breakdown at approximately 400 mV (Ag/AgCl) and no hysteresis loop. In other words, the protection potential for Co-Cr-Mo is coincident with the pitting potential, and no pitting takes place. In fact, the film breakdown for Co-Cr-Mo is a general dissolution of chromium oxide as the chromic ion (Cr^{3+}) becomes the hexavalent chromium ion (Cr^{6+}). When this occurs, the passive nature of the film is lost. There is no pitting susceptibility for this alloy in the unloaded condition and noncrevice environments. However, this alloy has demonstrated pitting and crevice corrosion under in vivo conditions, as is discussed later. The Ti-6Al-4V alloy also shows no pitting in this test in the potential range tested and shows negative hysteresis, indicating that the oxide film is enhanced by the increasing potential. However, titanium alloy also has

shown pitting and crevice corrosion in vivo (Ref 73).

It is worthwhile to note that the transpassive potential obtained from cyclic polarization testing is strongly dependent on the potential scan rate at which the testing is performed. Another shortcoming is that the reversing potential point is difficult to choose and may cause too much pitting propagation and modification of the localized chemistry and pit dimensions. On the other hand, it is found that pits can initiate and propagate under potentiostatic or potentiodynamic conditions far below the protective potential but with the slowest scan rate (Ref 74, 75).

There are other techniques that have been applied to the study of corrosion of implant alloys. These include tests to determine oxide film stability to potentiostatic challenge, that is, application of $+800$ mV (SCE) for a period of time that depends on the reaction (ASTM F 746), high-speed current monitoring at fixed potentials (potentiostatic testing) (Ref 76, 77), and galvanostatic test methods where fixed current densities are applied and the potential is monitored (Ref 78, 79). The work in Ref 76 and 77 is notable in that it showed evidence of current transients in titanium and Ti-6Al-4V that were ascribed to depassivation and metastable pitting.

In Vitro Solutions Used for Electrochemical Testing of Biomaterials. The in vivo environment can be approximated to first order as a saline solution (0.9% sodium chloride, NaCl); however, more complex aqueous solutions are also used. In particular, there are various proteins, cells, and other organic components besides inorganic salts that can be used. In addition, some chemicals will be produced in a special physiological process near the implantation sites, for example, hydrogen peroxide, nitric oxide, or other superoxides produced during inflammatory response that may be important (Ref 58).

Investigators usually use simulated physiological solutions to study the corrosion behavior of metallic biomaterials. These simulated solutions consist of inorganic constituents of body fluids, mainly sodium chloride with phosphate or bicarbonate to adjust the pH. Table 5 presents the compositions of artificial physiological solutions that are widely cited in the literature. These solutions are relatively simple yet representative

of the physiological environment. The disadvantage of these solutions is that they do not account for the presence of organic components. More recently, studies of corrosion and surface properties on biomaterials have been performed in more complicated solutions, where additions of proteins complement the saline solution (Ref 80, 81), serum saline solution (Ref 82, 83), saline with various concentrations of hydrogen peroxide solutions (Ref 84, 85), addition of cells to saline solution, culture medium and cell cultures (Ref 86, 87), and other solutions.

Direct Observational Corrosion Test Methods (Retrieval Analyses). There are several nonelectrochemical methods that can be used to obtain information about corrosion behavior of biomaterial surfaces and the presence and extent of corrosion debris in tissues adjacent to implanted metals. The examples are:

- *Microscopic examination of corroded surfaces:* scanning electron microscopy (SEM), atomic force microscopy (AFM), and transmission electron microscopy (TEM)
- *Analysis of surface chemistry:* Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS), and secondary ion mass spectroscopy (SIMS)
- *Analysis of solution chemistry:* atomic absorption spectroscopy (AAS) (Ref 88, 89)

Electrochemical testing typically cannot be performed in the human body, but some in vivo testing can be done in animals. Only very limited in vivo corrosion testing has been carried out in humans, including some reports on oral conditions (Ref 34). Retrieval and analysis of implanted medical devices and associated tissues is another important resource to understand in vivo corrosion properties on biomaterials (Ref 73, 90–93). In fact, ASTM F 561 (Ref 94) covers some recommendations for this topic.

The most detailed information on in vivo corrosion of biomaterials comes from retrieval studies (Ref 73, 91, 95, 96). Researchers (Ref 73) examined 148 retrieved total modular hip implants with mixed- (Ti-6Al-4V/Co-Cr) and similar- (Co-Cr/Co-Cr) alloy femoral stem and head combinations. They observed significant corrosion in both mixed- and similar-metal combinations; 16% of necks and 35% of heads in mixed-metal cases and 14% of necks and 23% of

Table 5 Compositions of biosimulated solutions

heads for similar-alloy cases showed signs of moderate-to-severe corrosive attack, and the corrosion process is progressive in time. This corrosion process has been described as mechanically assisted crevice corrosion attack (Ref 32). In a retrieval study (Ref 91), it was found that 89% of the plates and 88% of the screws of 250 stainless steel internal fixation devices showed evidence of pitting and crevice corrosion. Other researchers (Ref 97) examined type 316 stainless steel multicomponent devices removed from the human body and found that 91% had undergone visible corrosion, with crevice corrosion being the dominant form. More recently (Ref 96), 34 retrieval endovascular stents were analyzed, and 100% of the NiTi stents showed pitting; parts of the devices demonstrated other corrosion forms, such as surface craters. These studies revealed aspects of *in vivo* corrosion that had never been observed in *in vitro* testing. For example, pitting, etching, selective dissolution, and intergranular attack have been documented in Co-Cr-Mo alloys and stainless steels, and pitting and etching of titanium alloys has been documented (Ref 73).

Galvanic corrosion concerns the accelerated dissolution of one component of dissimilar-metal couples due to different nobility. The noble material will become the cathode, while the less noble one becomes the anode. The ratio of cathode to anode is very important for galvanic corrosion, where large cathode areas will produce a larger current density at the anode and enhance corrosion. However, it should be noted that galvanic corrosion happens only under specific potential conditions, for example, the pitting potentials or active dissolution potential ranges for the anodic electrode. For the three groups of biomaterials, all have wide passive potential ranges, and it is not likely that galvanic corrosion between these different couples presents a significant risk without other factors being present (e.g., mechanical disruption of oxides).

Mechanism of Localized Corrosion. Pitting, crevice corrosion, and mechanically assisted corrosion are forms of corrosion that can damage a biomedical device. On the other hand, ion release and other corrosion products formed by pitting and crevice corrosion may cause adverse host reactions.

Pitting results from the accelerated dissolution of metal in a region where the passive film has lost its protection due to breakdown or preferential dissolution of defects or inclusions. Pitting is an extreme and severe form of damage that can cause penetration into materials and/or produce a significant amount of metal ions. Crevice corrosion is, in fact, a variant of pitting but takes place in occluded areas or restricted geometries where the solution has more aggressive characteristics, such as low pH, higher chloride concentration, and low oxygen partial pressure (Ref 75).

Stainless steel is vulnerable to pitting and crevice corrosion, while titanium and its alloys

and Co-Cr-Mo are less susceptible (although not entirely immune) to these forms of corrosion. All three of these alloy types have experienced pitting and crevice corrosion *in vivo* (Ref 73, 91). Shape memory NiTi alloys show conflicting results for pitting corrosion resistance, where the alloy may or may not exhibit pitting. This variability mostly depends on the level of nickel in the oxide film (Ref 98). The Co-Cr-Mo alloy is resistant to pitting and crevice corrosion in the unloaded condition but is susceptible to them in the presence of mechanical stress, crevice conditions, and fretting (Ref 73).

Pitting and crevice corrosion result in the accelerated dissolution of metal in some sites due to breakdown of the passive film, while elsewhere, the film keeps its protective ability. According to research (Ref 74, 75), pitting and crevice corrosion result from the same mechanism, where one is initiated on open surfaces, while another occurs at an occluded site. Pitting usually possesses some different stages, including passive film breakdown, the nucleation of embryonic pitting, the growth of metastable pits, and the growth of stable pits (Ref 99, 100). The mechanism of pit nucleation is unclear, and some models propose the penetration of chloride ion through the film and dissolution of the metal (Ref 101), mechanical breakdown of the passive film (Ref 101–103), and local thinning of the oxide film due to chloride ion (Ref 101, 103). Recently, it was assumed (Ref 104) that breakdown of the passive film on transition metals is due to an electrical breakdown, by the Zener mechanism, where a high local current is created, generating heat, expanding the metal, and destroying the passive film. Several factors can influence the pitting behavior, including alloy composition, environment, potential, and temperature (Ref 75). In particular, the composition of the alloy and impurities in the passive film can play a crucial role in this respect (Ref 5). In addition to all these factors, another important aspect of corrosion behavior is mechanically assisted corrosion, for example, crevice corrosion of cobalt- and titanium-base alloys under fretting conditions. This is discussed in the article “Mechanically Assisted Corrosion of Metallic Biomaterials” in this Volume.

Corrosion Behavior of Stainless Steel, Cobalt-Base Alloy, and Titanium Alloys

This section describes the corrosion behavior of these three alloy systems. Because the corrosion behavior is governed by the oxide film, some comments on the dynamic aspects of oxide films are presented, then the corrosion behavior of 316L stainless steel, Co-Cr-Mo, and titanium alloys is presented.

Dynamics of Oxide Films on Metallic Biomaterials. Passive film formation on biomaterials is a dynamic process (Ref 105), and passive films are subjected to changes either in morphology or in chemistry with immersion,

with or without applied potentials in biological solution. *In situ* AFM results showed that passive films are subjected to reduction under cathodic potentials, for example, -1 V (Ag/AgCl) for 316L stainless steel in phosphate-buffered saline (PBS) (Ref 22) and -0.7 V (Ag/AgCl) for Co-Cr-Mo (Ref 20). Oxides on CP-Ti were not susceptible even at -1 V (Ag/AgCl) (Ref 19). At potentials that are close to the OCPs, stainless steel and Co-Cr-Mo developed domelike oxides. Under anodic potentials, but less than transpassive potentials, the passive films on 316L stainless steel, NiTi (Ref 22), CP-Ti and Ti-6Al-4V (Ref 106), and Co-Cr-Mo all showed oxide growth by lateral expansion of oxide domes. At transpassive potentials, the passive film of Co-Cr-Mo underwent fast dissolution, while CP-Ti showed film growth at higher potentials. At OCP, upon immersion in PBS, the oxide film became highly hydrated in terms of swelling of the oxide domes (Ref 107). Figure 5 shows the typical topographic changes by AFM technique of the surface of CP-Ti with immersion and electrochemical polarization.

The chemical composition of surface films on biomaterials is influenced by immersion and applied potentials. Researchers studied the surface composition of passive films formed on stainless steel (Ref 24), Co-Cr-Mo alloy (Ref 26), and Ti-6Al-4V alloy (Ref 28) in simulated physiological solution under various potentials using quasi *in situ* XPS. In their research, the samples were transferred, without contacting air, to the ultrahigh vacuum chamber for XPS analysis after oxidation in physiological solutions. They found that the predominant species for passive films on stainless steel are chromium and iron oxides, and oxides of nickel and molybdenum are also detectable in the passive film formed in this potential range. They attributed the enrichment of oxides in chromium and molybdenum in the passive film, strong enrichment of molybdenum, and depletion of iron at the alloy surface just beneath the passive film to the excellent corrosion properties for this stainless steel in physiological solutions. They found the passive potential range for Co-Cr-Mo alloy in simulated physiological solution extends from -0.3 to 0.6 V (SCE). When the potential is below 0.3 V (SCE), the main constituents of the passive film are oxides and hydroxides of chromium, while cobalt and molybdenum oxides entered the passive layer. The thickness of the passive film also increased when the anodic potential is higher than 0.3 V (SCE). For Ti-6Al-4V, the passive film consists of TiO_2 with a small amount of TiO and Ti_2O_3 in the passive potential range. Aluminum oxide (Al_2O_3) was incorporated into the TiO_2 layer and was mainly located at the oxide-solution interface. No vanadium oxide was detectable by XPS. In addition, results showed that complexing agents such as ethylenediamine tetraacetic acid and citrate have a big influence on the passivation for stainless steel and Co-Cr-Mo, and they enhanced the dissolution of nickel, iron, and cobalt.

Researchers (Ref 23, 108) characterized the surface oxides of stainless steel and Co-Cr-Mo in cell culture medium with and without cultured cells. They found the surface film on 316L stainless steel was enriched with iron and chromium oxides but depleted in nickel and manganese after immersion in these quasi-biological solutions. The Co-Cr-Mo alloy released cobalt, and the surface film consisted of chromium and molybdenum oxides. The passive film of titanium and Ti-6Al-4V consisted mainly of TiO_2 , and this film is stable in physiological conditions. However, the composition of the TiO_2 film may change by incorporation of ions and biomolecules from environments after immersion in physiological solutions (Ref 109).

As shown earlier in Fig. 4, 316L stainless steel is susceptible to localized corrosion attack, such as pitting or crevice corrosion, in physiological solutions, while the Co-Cr-Mo alloy undergoes more uniform film breakdown due to transpas-

sive dissolution of chromium oxide. Titanium and its alloys are usually ranked as highly resistant to corrosion in saline solutions; however, NiTi alloys do show breakdown of the passive film. There have been a large number of studies on the corrosion behavior of 316L stainless steel, Co-Cr, NiTi, and titanium alloys (Ref 37, 91, 110–115). Here, some typical results are reviewed and some new developments discussed. Emphasis is placed on topics such as effects of protein on corrosion behavior, influences of hydrogen peroxide on corrosion, and film behavior for these biomaterials. Further, some new insights are introduced on electrochemical and electronic characteristics on film behaviors using some novel approaches, such as electrochemical atomic force microscopy and step polarization impedance spectroscopy.

Corrosion of 316L Stainless Steel. Pioneer research (Ref 37) shows that 18Cr-10Ni-3Mo stainless steel is subjected to pitting and crevice

corrosion in Hank's solution at 37 °C (98.6 °F) and that the pitting potential ranged from 0.4 to 0.5 V (NHE). Further, the OCP for this alloy was measured in Hank's solution in vitro and in a goat in vivo. The values are close to 0.5 V (NHE) after longer times. The researchers concluded that this type of alloy does not resist pitting corrosion in body fluids for long periods.

Researchers (Ref 116) studied the polarization behavior of 316L stainless steel in Hank's solution and found that 316L is very susceptible to pitting and crevice corrosion in deaerated Hank's solution at 37 °C (98.6 °F) and that the film breakdown potential is close to 0.2 V (SCE).

The electrochemical behavior of 316L vacuum melted (VM) stainless steel and another high-nitrogen stainless steel (F1586 in Table 1) was tested in PBS and in a simulated crevice solution, using cyclic potentiodynamic and potentiostatic polarization measurements (Ref 115). Results showed that 316LVM is vulnerable to pitting, particularly during crevice corrosion, in PBS but that the high-nitrogen stainless steel (F1586) has no risk of pitting corrosion [$E_p > 1.10$ V (SCE), and E_{prot} is 1.04 V even in simulated crevice solution with higher chloride (2.5 M) and low pH (0.85) (E_p , 0.9 V; E_{prot} , 0.8 V versus SCE)]. It is interesting to note that although this alloy showed a small current peak at 0.65 V (SCE), which may correspond to the transpassive dissolution of Cr_2O_3 , the alloy repassivated at higher potentials. In other words, it is possible that high-nitrogen, high-chromium stainless steel has higher corrosion resistance than Co-Cr-Mo over a higher potential range.

Usually, the corrosion of stainless steel in chloride solution is related to its chromium (Ref 117) or manganese sulfide inclusion content (Ref 5). Changing of alloying elements can improve its corrosion behavior. Recent reports verified this point: high-nitrogen and/or high-alloy (chromium) stainless steel has superior localized corrosion resistance (Ref 118–120).

Corrosion of Co-Cr-Mo Alloy. The Co-Cr-Mo alloy also depends on the formation of a chromium oxide film to provide corrosion resistance, as occurs for the 316L stainless steel. However, it is well accepted that Co-Cr-Mo alloy has good corrosion resistance and is relatively immune to pitting and crevice corrosion in physiological solution (Ref 37, 121, 122) in the absence of mechanical abrasion. The reason for its good corrosion resistance may be related to the high chromium and molybdenum contents. In fact, at higher potentials, this alloy is subjected to general dissolution due to transpassive dissolution of chromium oxide. Another feature for this alloy (F75) is its relative lack of susceptibility to intergranular corrosion. It should be noted that this alloy is susceptible to pitting attack, crevice corrosion, and intergranular corrosion in some implants, particularly those where crevices are formed and mechanical abrasion (e.g., fretting) can occur. Under these conditions, the increased corrosion rate resulting from oxide film abrasion can accelerate crevice corrosion processes, raise

Fig. 5 Sequential atomic force microscopy images (contact mode, deflection image) of CP-Ti surface (etched sample, same spot). Scanning size, 5 μm ; height scale, 20 nm. (a) In air. (b) Immersion in phosphate-buffered saline, 1 day. (c) Two week immersion. (d) Four week immersion and after step polarization impedance spectroscopy testing; voltage, -1 to $+1$ V(Ag/AgCl)

metal ion levels locally, and lower pH such that pitting and intergranular attack may occur (Ref 73, 123, 124).

For stainless steel and Co-Cr-Mo alloy, chromium and molybdenum are essential alloying elements for imparting resistance to localized corrosion. The role of these two elements on corrosion resistance has been studied intensively. Researchers (Ref 125) used iron-chromium alloys with different chromium content and Fe-Cr-Mo alloys with similar chemical composition with 316L stainless steel in 1 M NaCl solution and measured the nucleation events of pitting corrosion, using micro-electrochemical methods. They found that chromium and molybdenum can decrease the magnitude of current transients, which leads to an earlier start of repassivation but does not change the repassivation kinetics. Studies (Ref 126, 127) found that molybdenum as an alloying element reduces the incidence of nucleation (breakdown of film) of metastable pits and further inhibits the growth of stable pitting.

Corrosion of Titanium. Titanium and its alloys are very resistant to corrosion in physiological solutions. The oxide film on titanium does not break down over a wide range of potentials. This alloy system has been heavily studied for its electrochemical behavior (Ref 81, 110, 112, 128–132) and reviewed (Ref 133). Unalloyed titanium and its alloys, including Ti-6Al-4V, Ti-Zr-Nb, and Ti-Al-Fe, have outstanding corrosion resistance in the absence of mechanical factors.

One exception is the nickel-titanium system of alloys based on the binary, equiatomic inter-metallic compound of NiTi. The corrosion properties of these alloys are of greater concern than CP-Ti or Ti-6Al-4V. There is a wide range of corrosion behavior reported for NiTi alloys due to the variability in the oxide film that forms (Ref 95, 98, 114, 134–136). When nickel can be removed from the oxide film, the film is primarily a TiO₂ film, similar to other titanium alloys. However, when nickel is present in the film (either in a metallic or oxide form), the corrosion resistance of the material is significantly reduced, and it has greater susceptibility to pitting corrosion, similar to that of 316L stainless steel.

Researchers (Ref 76, 77, 137) have indicated that titanium alloys are resistant to corrosion at the macroscopic level but not at the microscopic level. They used a microelectrode technique to study short-time duration current transients under potentiostatic conditions that they ascribed to the metastable pitting behavior for titanium and Ti-6Al-4V. They found very short-duration anodic current transients in both CP-Ti and Ti-6Al-4V and assert that this is evidence that the alloys are susceptible to metastable pitting under 0.5 V (Ag/AgCl) in Ringers' solution. However, AFM evidence (Ref 19, 138) appears to show that oxide domes can form and grow at the boundaries of extant domes and that these nucleation events may be the source of the current transients observed.

The NiTi alloy has been widely used in cardiovascular applications as a stent material due to its unique shape memory and superelastic properties. Studies on the corrosion properties of NiTi alloy were carried out by several researchers. However, the results of these studies are not consistent. It appears that the corrosion behavior of this alloy is heavily dependent on the chemical composition (Ref 98, 136), surface treatment (Ref 139), heat treatment (Ref 140), surface finish (Ref 141), and fabrication conditions (deformation state, etc.) (Ref 140). Most results agree that the corrosion resistance is closely related to the nickel content and state in surface films and inclusions (Ref 29, 136, 137, 142).

Mechanical Disruption of Oxides. Oxide film repassivation studies for the three different alloy groups are also very important for an understanding of localized corrosion properties with concurrent cyclic loading. Usually, passive current densities for these three groups of biomaterials are in the range of 0.1 to 5 $\mu\text{A}/\text{cm}^2$ when no mechanical disruption is present. It can increase approximately 6 to 8 orders of magnitude in current density when the film is disrupted mechanically (Ref 32) or during nucleation of a single pit (Ref 76). So, the repassivation ability will determine the corrosion property for these alloys in physiological conditions. Researchers (Ref 38, 143) studied the oxide fracture and repassivation behavior of Ti-6Al-4V and Co-Cr-Mo alloys in simulated physiological solutions using the electrochemical scratch test method (Ref 38, 143). In the case of mechanically assisted corrosion, mechanical motion will disrupt the passive film and expose the bulk metal to electrolyte, causing corrosion and ion release even during the process of repassivation of the film. This process will repeat under cyclic loading conditions (e.g., fretting or fatigue). In addition, fretting can cause local chemical changes, such as decrease of pH or increase of chloride, and make the environment more aggressive, enhancing further ion release (Ref 144). On the other hand, insoluble oxides and particles can be generated by fretting and other mechanical actions. The mechanism of fretting corrosion and mechanically assisted corrosion on biomaterials is discussed elsewhere (Ref 32) and in the article "Mechanically Assisted Corrosion of Metallic Biomaterials" in this Volume.

Mechanical disruption of oxides can also give rise to transient electric fields that can propagate away from the site of abrasion and may result in signals large enough to induce nerve firing (Ref 132).

Metal Ion Release from Metallic Biomaterials. From a thermodynamic point of view, all metal components of iron-base stainless steels, cobalt-base alloys, and titanium alloys are unstable in aqueous environments, and they tend to form metal ions that are released into solution. On the other hand, the formation of a passive film prevents ion release from the bulk material, but the passivation of biomaterials is

not completed in physiological solutions even after 1000 h for Co-Cr-Mo alloy and stainless steels, and after 100 days for titanium alloys, based on continuing changes in the OCP, which is a measure of the oxide film character. There exists ion and electron exchange reactions between the metal, passive film, and adjacent solutions. Ions, due to oxidation of alloying elements or dissolution of oxide film, can be released into the human body and may cause adverse host reactions. The sources for ion release can be categorized as: (1) localized corrosion; (2) preferential release (or selective dissolution); (3) passive dissolution; and (4) mechanically assisted corrosion.

Preferential release of alloying elements refers to the disproportionate release of ions, inconsistent with the composition of the alloy. For instance, it has been shown that iron and nickel preferentially release from stainless steel, cobalt from Co-Cr-Mo, nickel from NiTi, and aluminum and vanadium from Ti-6Al-4V. Studies indicate that the passivation elements, chromium and titanium, are dissolved into some biological media (Ref 145, 146).

Effects of Protein on the Corrosion Behavior of Three Alloy Systems. Another possible mechanism for ion release for biomaterials involves the influences of protein effects and superoxides. Researchers (Ref 147–151) found elevated concentrations of metals, including chromium, cobalt, and titanium, in the serum of patients with implants made from stainless steel, cobalt alloys, and titanium alloys. Furthermore, they found that proteins such as immunoglobulins in some molecular-weight ranges play an important role in binding to metals such as chromium.

Although studies on the corrosion behavior of these alloys in simulated body fluids (mainly ionic electrolyte) are extensive, there are relatively few studies on the corrosion behavior in protein-containing fluids. In fact, as mentioned earlier, the surfaces of these materials are always covered by a protein film immediately after implantation. It is difficult to determine the state of protein adsorption on metal surfaces and what effects these proteins have on the surface oxide.

Protein adsorption on metal (passive film) surfaces is very complicated, and the literature on this topic is somewhat limited and, in part, contradictory. Although different techniques, including labeling, optical, electrochemical, and microscopy, were used to study the adsorption of various proteins (mainly, albumin and fibrinogen) on metal surfaces, much controversy still exists (Ref 50). What is the nature of protein adsorption on metal surfaces? Is there non-specific or specific adsorption, and is the adsorption process electrochemical or not? What are the controlling factors that determine the protein adsorption on metal surfaces? All these questions remain, for the most part, unanswered.

In the case of corrosion of biomaterials in protein-containing solutions, most researchers used saline solutions with additions of albumin

or 10% serum, and the results are contradictory. Some studies have shown that the corrosion rate is increased by the presence of protein, for example, 316L stainless steel (Ref 152, 153), cobalt or Co-Cr-Mo (Ref 80, 154, 155), and titanium (Ref 79, 81). Other results show an opposite effect, for example, 316L (Ref 156, 157). There are even some results that show no significant influence (Ref 80).

Generally, if the amino acids or proteins do not form complexes with the metal in the passive film, these adsorbed molecules can act as inhibitors and prevent the release of metal ions into the body. Otherwise, the protein in solution could abstract already-oxidized metal from a protective oxide layer, rendering the underlying material liable to attack. Moreover, the protein may act as a catalyst or oxidizing agent for the metal with internal disulfide bonds, and the forming of a protein-metal complex may enhance dissolution of the material.

The role of proteins on the corrosion behavior of biomaterials remains unclear. Particular proteins and their interactions with the surface may be more important than others in affecting corrosion. For example, the effect of fibrinogen may play a central role in various biological processes and may be more likely to cover surfaces than other proteins.

Effects of H_2O_2 on Corrosion and Oxide Behaviors of Implant Biomaterials. During the inflammatory process that typically follows implantation of a metallic device, macrophages can secrete hydrogen peroxide (H_2O_2) and other free radicals, which subsequently form hydroxyl radicals, and superoxide and other active species (Ref 158, 159). Hydrogen peroxide can be a strong oxidant or may also act as a weak reducer, as seen in the following equations:

It is known that metal ions can decompose H_2O_2 and create free radical OH^\cdot by the Fenton reaction, and this free radical is harmful to tissue. For titanium (TiO_2) surfaces, the unique property of this material is that it can form a gellike matrix and trap the free radical during decomposition of H_2O_2 , and this may help to explain its good compatibility.

The effects of H_2O_2 on structure and corrosion behavior have been studied for titanium, while almost no work has been done on stainless steel or Co-Cr-Mo alloy. Studies (Ref 39, 60) showed that H_2O_2 largely increased the OCP of CP-Ti in PBS with the addition of H_2O_2 in the range from 1 to 100 mM, as well as the corrosion rate. In addition, H_2O_2 decreased passive film thickness and led to a granular structure. Furthermore, H_2O_2 decreased the dissolution/oxidation resistance of titanium in PBS solution and resulted in a more pronounced two-layer structure of the oxide.

Researchers (Ref 160) reported a study on the effect of H_2O_2 concentration on 316L stainless steel in seawater, and they found that 316L has a higher OCP in summer, approximately 0.6 V versus SHE compared with 0.3 V in winter. Correspondingly, the concentration of H_2O_2 is higher in summer (>10 ppm) than in winter (<2 ppm).

Electrochemical impedance spectroscopy (EIS) has been used more recently to evaluate corrosion and electronic properties of biomaterials (Ref 91, 161–163). In this method, an electrical perturbation (usually voltage) is applied to the electrochemical interface, and the resulting current response is recorded. There are several different electrical stimuli that can be used in impedance spectroscopy research. The most commonly used technique is to apply a small-amplitude (usually less than 20 mV) sinusoidal voltage bias around the fixed direct current potential (usually OCP) in a range of frequencies (typically 1 mHz to 1 MHz) to the interface and measure the current, which also exhibits a sinusoidal waveform but with a phase shift. The advantage of this method is the availability of instruments and the nondestructive nature of the test. It is, however, time-consuming, particularly in the low-frequency range. Another approach is to apply small incremental steps in potential to the electrochemical interface and measure the current transient response. Correspondingly, the frequency-dependent impedance characteristics can be obtained from time domain current response via the Laplace transform technique. This method was first used (Ref 163) in biomaterials studies (step polarization impedance spectroscopy, or SPIS). The advantages of SPIS are that the impedance information can be determined over a range of potentials concurrently with the polarization behavior, and further, this technique is easy to use as well as fast and inexpensive compared with traditional commercially available electrochemical impedance testing instrumentations.

All impedance techniques have the capability to provide information about the electrical characteristics of the interface between the biomaterial surface and the environment. Generally, the interface of biomaterials in physiological solutions can be modeled as a Randles circuit, where a resistor (polarization resistance) is connected in parallel with a capacitor (double-layer capacitance), and they connect with another resistor (solution resistance) in series. Sometimes, this circuit needs to be more complicated; for example, the passive film can be considered as a two-layer structure in the case of existing H_2O_2 for CP-Ti in PBS (Ref 39), and nonideal circuit elements are needed.

Researchers (Ref 84) studied the surface structure of CP-Ti in PBS with or without addition of H_2O_2 , and they found the capacitance and polarization resistance changed with the addition of H_2O_2 and immersion times. Other scientists (Ref 162) studied the corrosion behavior of 316L

stainless steel, Co-Cr-Mo, and Ti-6Al-4V in physiological solutions at pH 1 and 6.2. They found 316L corroded at pH 1 after a 20 h immersion, while Co-Cr-Mo exhibited slight corrosion in the early stage, and Ti-6Al-4V kept its passivity, but the dissolution rate increased compared with that at a pH of 6.2. In pH 6.2, all alloys remained passive. Another advantage of EIS is that it can be used to study the electronic semiconducting structure of passive film (Ref 164) using the Mott-Schottky equation, which measures the capacitance under different potentials at a fixed frequency. Information gained from these tests includes values of the flat band potential and the density of charge carriers that may be related with the corrosion property of biomaterials.

In SPIS, all impedance information can be collected in a relatively short time (within 30 min) in a large potential range (usually from -1 to 1 V versus Ag/AgCl), as well as the polarization behavior (Ref 163). In addition to capacitance and polarization resistance, the film resistance can be obtained. Moreover, this method can be combined with AFM methods to obtain information on morphological changes as well as electronic changes of the passive film, with potential for various biomaterials in solution (Ref 22, 138). A researcher (Ref 163) studied the electrochemical impedance behavior of platinum, CP-Ti, and Co-Cr-Mo in PBS, using the SPIS method. He found that the impedance characteristics, including film resistance, polarization resistance, and capacitance for platinum in solution, showed only one major transition in the vicinity of -500 mV (Ag/AgCl) and are otherwise relatively constant; the film resistance increased and capacitance decreased with increasing potential for CP-Ti, and this indicated film growth for this material with increasing potential. For Co-Cr-Mo alloy, the film resistance increased with increasing potential first but dropped near the transpassive potential range, while capacitance dropped first and increased later. All these results showed that SPIS is a powerful method to evaluate the electrochemical and electronic behavior of biomaterials in physiological solutions.

Biological Consequences of In Vivo Corrosion and Biocompatibility

All metallic biomaterials corrode in physiological conditions, either in passive dissolution or in localized corrosion or mechanically assisted corrosion. All these corrosion processes release metal ions or generate various particles or debris. The host will react to these foreign bodies and may cause adverse reactions. In fact, the biological consequences of in vivo corrosion are not well documented. A brief introduction is given, and more information can be found in some review papers (Ref 150, 165, 166).

Local and Systemic Distribution of Ions and Particles. It is well documented that corrosion products can be found in the tissue

surrounding the metallic biomedical devices (Ref 165). Around the stainless steel internal fixation devices, particularly at the screw-plate junctions, two kinds of corrosion products were identified: iron-containing hemosiderin-like granules and chromium-containing particles (Ref 167). In addition, similar corrosion products have been reported in the tissues around stainless steel femoral stems and spinal instrumentation.

Researchers (Ref 168) analyzed the corrosion products at the modular junctions of total hip implant and the migration of these solid products to the periprosthetic tissue, using electron-microprobe energy-dispersive x-ray analysis and Fourier transform infrared spectroscopy. They found two distinct corrosion products. The principal corrosion product is an amorphous chromium orthophosphate hydrate-rich particle, which presented at the modular head-neck junction as a precipitate of chromium with phosphorus from the fluids. These particles are still found within the bone-implant interface membranes and adjacent pseudocapsules. Another form of corrosion product is a highly crystalline interfacial layer of mixed oxides and chlorides and is located in the crevice areas formed by the mated neck and head; it is rarely found in the surrounding tissues.

The corrosion products found in local tissues around titanium alloy prostheses are usually in the form of particulates or small debris, and they appear to be corrosion-wear products. Researchers (Ref 169) found that the debris in tissue has a similar chemical composition with that of the bulk material (Ti-6Al-4V), indicating that these debris represented wear particles rather than precipitated dissolution products, which usually are associated with iron- and cobalt-base alloys. Other scientists (Ref 170) found metal particles whose constituents were proportional to their bulk composition after examining a retrieved total hip prosthesis made of Ti-6Al-4V and ultrahigh-molecular-weight polyethylene. Another possible reason for this debris for titanium alloy implants may be the result of oxidation of titanium due to superoxides (Ref 60), or metastable pitting dissolution (Ref 76), or wear.

Metal ions may bind to proteins and be transported in the bloodstream or lymphatics to remote organs. In fact, multiple biomaterial alloying elements were found in serum and urine. Studies (Ref 151) found that four years after total knee replacement with a titanium-base alloy component, there was a tenfold increase of titanium concentration in the serum, compared with a control patient who had no implant. Particularly for those patients who had failed implants, the titanium levels in the serum were 2 orders of magnitude higher than that of the control. Similarly, after 6 to 120 weeks implantation of a total knee replacement, researchers (Ref 171) found an increased cobalt level in the serum and an apparent increase for two patients who had loose prostheses. In fact, elevated metal ion levels are not found only in people with failed implants.

Researchers (Ref 172) reported that chromium levels in serum and urine increased five- and eight-fold in patients with well-functioning total hip replacements.

Biological Response for Ions and Biocompatibility. It is well known that some quantity of metal ions is essential for biological processes, and they have functional forms and fairly constant concentrations (Ref 173). These essential elements include some metallic biomaterial constituents such as iron, cobalt, molybdenum, chromium, manganese, vanadium, and nickel. Other main constituents of metallic biomaterials belong to the nonessential elements, with highly variable concentrations in the body, and are more likely to be dependent on the contacting environment, for example, aluminum, titanium, zirconium, niobium, tantalum, and others. Metal ions or debris originated from biomedical devices may cause adverse host response via complex reactions and may trigger allergic, immune, and inflammatory reactions (Ref 174).

Toxicity of metal ions depends mainly on their concentration and compound forms (Ref 175); for instance, essential elements such as cobalt and nickel can induce toxic reactions at high or excessive concentrations. In addition, the nature of metal compounds plays a crucial role in their toxic and other adverse responses. For example, Ni_3S_2 is highly carcinogenic, while NiCl_2 is not (Ref 174). The pure metal is rarely toxic, and the metallic form of these elements is rarely seen in physiological conditions, particularly for biomaterial alloying elements. Thus, for the same metal, the oxidation state determines its toxicity; for example, hexavalent chromium (Cr^{6+}) is more toxic than trivalent chromium (Cr^{3+}).

Although some cases of allergic reactions have been reported, and cancer formation may be related to implantation, no systematic study exists to evaluate immunological or carcinogenic reactions to implantation of metallic biomedical devices. Researchers (Ref 176) found that people from an implant population group were sensitized to the allergens of nickel, chromium, and cobalt at a rate of 9.6, 9.3, and 6.0%, respectively. This number is higher than that of the general population, where sensitivity is 4.2, 1.7, and 1.4%, respectively. Indeed, the long-term biological effects of these alloying elements or their compounds are currently unknown.

Summary

The benefit of application of metallic biomedical devices is clear, and metallic biomaterials will continue to be used in orthopedic, cardiovascular, and other medical applications for the foreseeable future. Corrosion of biomaterials plays a central role in the success or failure of these biomedical devices. Corrosion may cause device failure directly, such as penetration, fracture of biomedical devices, or induced acute adverse host reactions by the corrosion product. Corrosion is an extremely

complex process and involves the electrochemical and chemical reactions between material and environments. In addition, the human body is also a complex bioelectrochemical and biomechanical environment with dynamic loading actions and biochemical variation. All of these factors will interact with the implantation of biomedical devices, and the interplay of these physiological processes with corrosion will continue to be a source of investigation for the foreseeable future.

Corrosion Fatigue and Stress-Corrosion Cracking in Metallic Biomaterials

Kirk J. Bundy, Tulane University
Lyle D. Zardiackas, University of Mississippi Medical Center

AS THE FIELD OF BIOMATERIALS SCIENCE proceeds into the 21st century, many changes are taking place. Traditionally, biomaterials have been defined as materials that show physical, mechanical, electrochemical, and, most importantly, biological properties that are compatible with hard and soft tissues that they replace or augment in some manner. Recently, there has been an emphasis on the area of development of biological materials. Along with this emphasis has come a redefinition by some of the term *biomaterials*. The topic of this article is consistent with the traditional definition of biomaterials science and specifically addresses some of the mechanical/electrochemical phenomena related to the *in vivo* degradation of metals used for biomedical applications. The areas addressed here are the properties and failure of these materials as they relate to both stress-corrosion cracking (SCC) and corrosion fatigue (CF).

Because biological systems behave dynamically, both on a macroscopic and microscopic level, and because interference with both the anatomy and physiology of patients must be kept to a minimum, materials and devices must be produced and evaluated in a substantially different manner than is done for systems used for other engineering applications. As an example, when replacing or repairing a piece of machinery, there may be limitations on materials, size, and methods of repair; however, the part or the entire device may be replaced. This possibility is not available when dealing with a human being. There are many more limitations on the materials placed in a biological system, some of which include biocompatibility, stress shielding, and limitations on device dimensions due to patient anatomy. Each of these potential problems has a profound effect on the material out of which a device may be made, which is not the case for materials used for other engineering applications. Additionally, since these materials are placed in a living, changing biological system where these changes cannot be predicted in a precise manner, because they are a function

of the individual host, the task is to choose materials that are the most appropriate compromise, keeping in mind that the biological interactions with the patient are of supreme importance.

This leads to the important concept of implant material/device failure. While there are several mechanisms by which metallic load-bearing implants may not achieve their intended goal, the primary engineering-related mechanisms are by wear, corrosion, fretting corrosion, CF, and SCC. Should fracture occur, the primary mode has been identified by numerous investigators as fatigue, which is often exacerbated by the corrosive nature of the physiological environment. Others have suggested that fracture may, in some cases, be due to SCC, especially during the crack propagation stage. These observations make an understanding of both SCC and CF fundamentally important to everyone in the industry, including, but not limited to, primary metal suppliers, device manufacturers, and surgeons who place the implants. In light of these observations, this article deals with both SCC and CF of metals used for implants.

Background

This section considers necessary background information pertinent to understanding factors related to the use of surgical implants and their deterioration in the body environment. These include both biomedical aspects such as active biological responses and the chemical environment characterizing the internal physiological milieu, as well as electrochemical fundamentals needed for characterizing CF and SCC.

Biomedical Aspects

Reasons for Interest in Environmentally Assisted Cracking of Load-Bearing Implants. Metallic implants have been used to help patients for well over a century. Over the years, a great deal of research has focused on

corrosion of such devices and of the materials used to fabricate them. This effort was examined in a 1994 review article (Ref 1). The vast majority of this effort is not motivated by concerns related to engineering failures of structures in the usual sense (i.e., failure by fracture). Rather, the focus is predominantly on various adverse biological reactions (inflammation, allergic reactions, carcinogenesis, etc.) that might be related to or a consequence of release and then subsequent transport of metallic corrosion products (in either ionic, complexed, or solid forms) within the body. Such effects will undermine the biocompatibility of an implant material and are the design limits that restrict the selection of metals for *in vivo* use more often than mechanical property concerns. Corrosion fatigue and SCC are important exceptions to this situation. Here, the primary concern is not the biological effects of anodic dissolution, but rather how the presence of these materials in relation to human anatomy and physiology affects the ultimate mechanical failure of the implanted device.

The influence of mechanical forces on corrosion behavior of implant alloys is complex. Effects of stress-enhanced ion release (SEIR), for example, can be observed under conditions of static and dynamic loading, time exposure, and polarization that do not cause failure by fracture (Ref 2–4). Stress-enhanced ion release refers to an increase in the rate of corrosion or susceptibility to corrosion (a lowering of breakdown potential in 316L stainless steel in Ringer's solution almost to the free corrosion potential, for example, as discussed in Ref 5) due to applied stresses. This arises from breaches in the integrity of the passive film on a microscopic scale due to plastic deformation. The effect of mechanical stress on deterioration of implant materials by corrosion processes thus should be viewed as a continuum ranging from SEIR to environmentally assisted cracking. The focus of this article is on the more severe end of this spectrum, CF and SCC. Such cracking is possible since implanted devices can be highly

loaded. For example, the load on a weight-bearing joint may be as much as 4500 N (1000 lbf) (Ref 6).

Biological Factors. The major difference between corrosion fatigue and stress-corrosion cracking *in vivo* and in the other engineering environments where they can occur is the fact that there are a number of active biological factors and processes that occur in the body that can alter the loads applied to implants, and even the environmental chemistry, sometimes in dramatic ways. Some of these factors are discussed in this section.

Stress Shielding and Bone Resorption. Unlike metals, bone is a growing tissue whose growth is regulated, in part, by the mechanical stresses placed upon it. When loads applied to bone diminish below normal physiological levels, or increase above certain levels, cells in bone, known as osteoclasts, react by locally destroying bone mass. When osteoclastic activity predominates over osteoblastic (bone-forming) activity, net resorption of bone results. So, in situations such as space flight (where there is a lack of gravitational stress), bed rest, prolonged lack of exercise, or when the load is increased above certain levels such as in orthodontic treatment, the volume of bone and/or bone density may decrease. When resorption has progressed far enough and loads on bone are suddenly increased, fractures can result, a phenomenon often seen in osteoporotic patients.

Since the loads on the skeletal system are substantial, surgical implant devices used to temporarily or permanently replace bone function must have adequate tensile, compressive, and bending strength values and be superior in regard to other mechanical properties as well. This means that high-load-bearing orthopedic implants usually are fabricated from metallic biomaterials (and, to a lesser extent, from ceramics).

From the materials science viewpoint, bone is a composite material made up predominantly of a polymeric protein, collagen, and a mineral phase, hydroxyapatite (HA), $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. The Young's modulus of bone is approximately one order of magnitude below that for common implant alloys such as stainless steel, titanium, and cobalt-base systems. When a composite engineering structure (in this context meaning a bone with an implant) is subjected to mechanical loads, the stiffer component will be the main stress-bearing member. For an orthopedic device, this means that the higher modulus metal bears the predominant portion of the load, while the load on the bone is diminished compared to what it would be under normal physiological conditions. This effect is termed stress shielding (or, sometimes, stress protection).

In certain cases, stress shielding is a positive phenomenon. For example, when a fracture fixation plate is used as a rigid internal splint to treat a bone fracture, the initial relative lack of stress on the bone and the rigid stability of the

construct allow healing of the fracture to begin. A certain amount of stress is required to stimulate adequate bone healing, however, and the fracture fixation plate, by allowing early weight-bearing on the part of the patient, helps to accomplish this. On the other hand, if stress shielding is severe enough, bone healing may be delayed and bone resorption can even occur (Ref 7). This can lead to implant loosening. Also, in the bone adjacent to a prosthesis such as a total hip replacement (THR), as the amount of bone structure that can serve as a support for the femoral component of a THR diminishes, cantilever bending loads on the device can increase substantially. This may eventually lead to premature fatigue or CF failure of the device.

Fracture Healing/Nonunion. Though most bone fractures are treated by manipulation and plaster cast fixation (Ref 8), often internal fixation devices are needed. Rigid stability and a vascular supply to the fractured bone that is intact are essential requirements for normal fracture healing (Ref 9). Compression between bone fragments serves to enhance stability, but in itself does not promote bone remodeling. While micromotion, or cyclic loading and unloading below a certain level, may enhance healing of bone, if macromotion at the interface occurs, delayed healing or nonunion of the fracture will result, and a pseudoarthrosis will be formed. In this case, an implant will be subjected to a variable load spectrum with high and prolonged loading conditions (a scenario that it is not designed to withstand), and fatigue fracture can often occur. Other adverse events and situations associated with implant instability that can lead to such failure include malreduction, bone defects and necrosis, delayed healing, secondary fracture, pathological conditions, and infection (Ref 10, 11).

Difference Between the Environment in the Oral Cavity and the Internal *in vivo* Milieu. The chemical composition of various body fluids with which metallic biomaterials can be in contact may differ substantially in key aspects. Table 1 shows ionic contents of blood plasma, extracellular fluid, and saliva; dissolved gas concentrations in arterial blood, venous blood, and interstitial fluid; and organic constituents in plasma and saliva.

The primary, though not the only, chemical variable that affects *in vivo* corrosion is the chloride ion concentration, due to its influence on integrity of passive films (discussed later). The chloride content in the internal body milieu is much higher than in saliva, which means that the internal environment of the body is much more aggressive compared to that found in the oral cavity. This difference accounts to a significant degree for the much wider spectrum of metallic materials used in dentistry, as opposed to in orthopedic or cardiovascular surgery. The protein moiety is also very important, since proteins will adsorb onto the surface of all metallic biomaterials and can exert substantial influences on corrosion processes.

Pertinent Fundamentals of Corrosion and Electrochemistry

As indicated previously, the service environment in the body is rather complex, and the specifics regarding inorganic and organic chemical composition, as well as active biological responses, applied loads, and so on, can have an impact on the corrosion resistance of implant alloys. Bundy (Ref 1) has considered these topics more completely. Here, aspects of corrosion science that are pertinent to the influence of the environment on the mechanical failure of metallic implant devices are briefly reviewed.

Body pH, though varying from one location in the body to another, is basically set by homeostatic regulation, usually to a value, or narrow range of values, on the slightly alkaline side. Under these conditions the cathodic reaction is reduction of dissolved oxygen:

Acidic conditions can develop in pits, however, and such environments can also exist temporarily when normal physiological processes are upset at locations where inflammatory reactions are underway. In such situations, other reduction reactions might be pertinent:

All body solutions contain organic substances, and many contain quite a number of proteins. Generally speaking, these will interact with a foreign surface that is presented to the body through both hydrophobic and electrostatic forces that on balance serve to attract the proteins to the interface, where they will adsorb onto it, as pointed out previously. These may exert an inhibitory effect on corrosion in some cases, while accelerating corrosion in others.

Pertinence of Passive Films and Their Disruption. Though some biomaterials will derive their corrosion resistance through the mechanism of thermodynamic immunity (those that contain large proportions of gold, platinum, and palladium, for instance), the vast majority of implanted devices achieve their corrosion resistance (and biocompatibility) because they develop a passive film that maintains its integrity under *in vivo* conditions. A convenient way to visualize the conditions that allow passivity for a given metal is the potential-pH diagram, also known as a Pourbaix diagram. Figure 1 provides a specific example for an element of importance (cobalt) for fabricating surgical implants. Most published Pourbaix diagrams assume that the electrolyte is pure water. There are computer calculation programs that can determine the appearance of the diagram for a selected electrolyte composition, though, and accounting for the difference between pure water and a more realistic electrolyte better simulating body conditions is important for understanding the behavior of metallic biomaterials in the body (Ref 13).

Most, but not all, of the corrosion mechanisms found to be important for alloys serving in industrial environments have also been found to occur under some circumstances *in vivo*, for example, pitting, crevice corrosion, intergranular corrosion, galvanic corrosion, fretting corrosion, and the subjects of this article, CF and SCC. Many of these phenomena, the latter two in particular, are related to the stability of the passive film on the biomaterial.

When using a Pourbaix diagram to assist in prediction of potential corrosion problems, it should be kept in mind that for localized corrosion processes, such as pitting, crevice corrosion, and SCC, the chemical conditions that are established within the occluded cell can dramatically differ from those in the bulk. For example, in dilute near-neutral chloride solutions, the environment within a pit has been seen to be

quite acidic and highly concentrated regarding chloride content.

Besides the Pourbaix diagram, a theoretical construct, one of the best graphical means for visualizing electrochemical conditions that foster passive layer stability is the experimental potentiodynamic polarization curve. An example for an active-passive material is shown in Fig. 2. The zones of borderline passivity where the electrode potential is such that material would be most vulnerable to SCC are indicated in the figure.

In addition to just placing an alloy in a vulnerable region, as shown in Fig. 2, electrode potential can have additional substantial impact on environmentally sensitive failure processes. The exact influence is dependent on the corrosion mechanism involved. For example, if hydrogen embrittlement (HE) plays a role in the

failure process, then cathodic polarization (which would increase hydrogen production) would generally accelerate the rate of crack growth, and anodic polarization would retard it. Hsiao et al. (Ref 14) point out circumstances where cathodic polarization can raise pH, however, which would inhibit hydrogen ingress into the lattice and thus not necessarily lead to heightened embrittlement. On the other hand, if the static or dynamic cracking involves mechanisms controlled by film rupture/anodic dissolution or anionic adsorption (discussed later), then the effect of polarization would be reversed (Ref 15), with anodic polarization raising the rate of crack growth and cathodic polarization decreasing it. Reported effects of variables such as oxygen content, ionic concentration, flow rate, pH, and alloy composition can often be traced to their effect on electrode potential (Ref 15, 16).

Table 1 Concentrations of ions, dissolved gases, and organic compounds in body fluids in contact with metallic biomaterials

Ion	Ionic components, mM		
	Blood plasma	Extracellular fluid	Saliva
Anions			
Cl ⁻	96–111	112–120	15.0–24.8

Metallic Biomaterials

As pointed out previously, metallic biomaterials are widely used throughout the body in many applications to aid in healing of bone, to functionally replace diseased or injured tissues, and to interfere with the progression or consequences of many disease conditions. This section briefly reviews those materials and alloy systems that have been studied either under laboratory conditions or in animal experiments regarding their susceptibility to CF or SCC, and/or for which reports exist from retrieval studies indicating such susceptibility. Because of biocompatibility concerns, only three alloy systems have so far seen widespread *in vivo* use in orthopedics and other areas. These are stainless steels, cobalt-chromium-base alloys, and titanium-base alloys. In this section both the applications and the alloy systems are briefly surveyed. Further information on these materials, when used for bone fracture fixation, is given by Tencer (Ref 17). Shetty and Ottersberg (Ref 18) also provide further detail on these materials and give a description of the history of their use in surgery. In some applications, to achieve secure biomechanical fixation, porous-coated layers that spur tissue ingrowth are sometimes used, as described below. Though many different alloy systems are used in dentistry (Ref 19), the main one for which there are concerns regarding corrosion and fatigue is dental amalgam. This material is discussed in the last portion of this section.

Uses in Various Surgical Specialties

Metallic biomaterials are used in a great many surgical implant applications, which are mainly focused in the fields of orthopedic and cardiovascular surgery and dentistry. In some situations, biomaterials serve as temporary implants (fracture fixation devices that act as a rigid internal splint, for example) or as permanent replacements for body tissue that is surgically

excised (an artificial total hip replacement, for example). Another important orthopedic application is the use of metallic rods and other devices designed to correct spinal deformity (Ref 6). Selected applications are considered in this section.

Orthopedics. Stainless steels are the most widely used orthopedic material; however, of the three alloy systems most commonly used, the stainless steels are the least corrosion resistant. Consequently, they are more commonly used for implants that temporarily serve in contact with *in vivo* fluids (e.g., fracture fixation plates), as opposed to internal prostheses such as artificial joint replacements. Depending on the degree of cold working, a range of mechanical properties is available to the implant designer, as described more fully below. When maximum ductility is needed and a moderate strength is tolerable (e.g., for cerclage wires or certain reconstruction plates), annealed material is often preferable (Ref 20). Cold-worked stainless steel is appropriate for bone plates and screws and intramedullary nails, while stainless steel that has been highly cold drawn (extra hard condition) would be employed for situations requiring maximum strength (e.g., Kirschner wire and Schanz screws) (Ref 20).

Based on their high corrosion resistance in the *in vivo* milieu, both titanium alloys and cobalt-chromium (Co-Cr) materials are often employed to fabricate total joint replacements. These joints are articulating, however, and so the wear resistance of the materials comprising the wear couple is quite important. Titanium alloys have relatively poor wear properties compared to Co-Cr materials, so the cobalt-base alloys are more commonly used for articulating metallic components of total joint replacements. Surface-hardening procedures such as nitriding, while improving the wear resistance of titanium-base orthopedic biomaterials, still do not produce materials as wear resistant as the cobalt-base alloys. Additionally, Rodriguez et al. (Ref 21) have shown that nitriding of Ti-6Al-4V reduces low-cycle fatigue strength by 10%.

In part for reasons related to the issue discussed in the prior paragraph and in part for reasons of surgical convenience, since around the 1980s, the modular artificial joint concept has become increasingly widespread, particularly for the artificial hip. Here, the head of the femoral component is fabricated from a cobalt-base alloy (to optimize wear resistance of the device) and its stem is made from extra-low interstitial (ELI) Ti-6Al-4V (the alloy of greater strength and fatigue

resistance). Though this arrangement creates a galvanic couple, it was originally thought that since both materials were passive, corrosion problems would not be of concern (Ref 22). However, a rather high frequency of severe corrosion of such devices was often observed (Ref 23), for reasons thought by some as due to a fretting-assisted crevice-corrosion mechanism (Ref 24).

Though the stainless steel, cobalt-base, and titanium-base alloy systems account for virtually all of the metallic devices used in orthopedics, there has been some interest in using other metals, such as tantalum and niobium, but mechanical properties of these materials are limiting factors. A zirconium-base alloy containing 2.5 wt% Nb has also been developed for orthopedic (knee implant) applications (Ref 25).

Dentistry. Many alloy systems are used in dentistry in a range of applications including fillings, wires, crowns, bridges, removable partial dentures, single tooth implants, and so forth (Ref 19). These include gold and gold alloys (including also white gold and low gold compositions), base metal alloys (based on Co-Cr and Ni-Cr systems), materials of the type discussed below (e.g., austenitic stainless steels such as 316L, commercially pure (CP), titanium and Ti-6Al-4V, and Nitinol), Elgiloy, β -titanium, dental amalgam, tantalum, and others (Ref 19, 26, 27). In terms of the themes most germane to this article—corrosion, fatigue, and deterioration due to applied stress—the material of most interest in this regard is dental amalgam, which is discussed in more detail below.

Cardiovascular Surgery. Metallic materials do not play nearly as great a role in cardiovascular surgery as they do in dentistry and orthopedics. Here, polymers are the main class of biomaterials that are used. Yet there are

Fig. 1 Pourbaix diagram for cobalt

Fig. 2 Polarization curve and how it relates to vulnerability

certain applications where various alloys have been and are employed to treat serious and even life-threatening disease conditions afflicting the heart and circulatory system; artificial heart valves, pacemaker leads, and stents, for example.

To consider these briefly, older designs of artificial heart valves used to treat incompetence and stenosis of natural valves in the heart were based on ball and cage designs. Polymers were used for the occluder and sewing ring, but the cage (consisting of a metallic ring and wire struts) was usually made from Ti-6Al-4V ELI or Co-Cr alloys. The Björk-Shiley valve considered later also had a Co-Cr frame and used a carbon disk occluder. Cardiac pacemaker leads inevitably must be made from electrically conductive materials. Some designs have used porous metals at the ends of the leads to foster fixation of the electrode to the heart by tissue ingrowth into the pores. Though stresses are not high in this application, the leads will experience 3 to 4×10^7 heartbeats annually and should last for many years, so strong and highly corrosion-resistant biomaterials should be used. Materials used to fabricate pacemaker leads and electrodes have included stainless steel, platinum-iridium (Pt-Ir), stainless steel plated with gold or platinum, silver-palladium, and cobalt-base alloys (Elgiloy and MP35N) (Ref 28). Fatigue failures of pacemaker leads have occurred. Elgiloy and Pt-Ir have been the most successful materials used. Elgiloy is more fatigue resistant, but corrodes more. The likelihood of such failures can be diminished by geometrical changes in the design of the lead wires. These new electrodes combine both of these biomaterials in geometrical configurations that provide sturdy pacemakers with superior fatigue resistance. This approach, however, might lead to a worse corrosion situation due to the use of dissimilar metals and the possibility of galvanic coupling.

Stents are a much newer application for metals in the cardiovascular system, one that has become widespread only in the last decade or so. These devices consist of a thin tubular cage that is used to reopen a blood vessel suffering from partial occlusion of the lumen. Generally, they are put in place and expanded using a balloon angioplasty procedure. Such coronary stents have mainly been made from 316L stainless steel, ASTM F 138 (UNS 31673), see the section "Stainless Steels" below. It is essential, however, that the stent be visible on radiographs. This can be problematic for stainless steels in thin sec-

tions. Using metals of higher atomic number can alleviate this problem, since materials become more radiopaque for higher atomic numbers. The desired degree of radiopacity can be achieved either by using alternative materials, tantalum for example, or else by alloying the basic stainless steel composition with about 5 to 6 wt% Pt (Ref 29, 30).

Stainless Steels

At various times in the past, 302, 304, and 316 stainless steels were used as implant materials. Gradually, 316L became the most commonly used of these and is still in use today. Stainless steels such as 316L cannot be hardened by heat treatment, since they are austenitic and could become partially or fully ferritic, but they can be readily work hardened. There are four compositions of contemporary stainless steels for which implant alloy standards have been developed, as shown in Table 2. The addition of molybdenum to the steel helps to minimize pitting corrosion susceptibility. For 316L stainless steel (ASTM F 138), the composition index ($\%Cr + 3.3 \times \%Mo \geq 26.0$) is a quantitative measure of resistance to pitting corrosion known as the pitting resistance equivalent (PRE) (Ref 20). This material is totally austenitic, nonmagnetic (thus free from movement or tissue heating effects when magnetic resonance imaging, or MRI, scanning is performed), and without delta-ferrite, chi, or sigma phases. The other materials are also ferrite-free (to improve resistance to corrosion), and all alloys meet stringent microcleanliness standards (due to the limitations on sulfur and silicon content and vacuum arc remelting, or VAR, or electroslag remelting, or ESR). The limitation on silicon also retards the rate of formation of sigma phase, which can lead to embrittlement for certain heat treatments (Ref 31). The grain size is specified as ASTM 5 or finer for 316L. The reader is referred to the original standards for the details of these microstructural requirements and for further information on other characteristics of these biomaterials. Murty (Ref 32) has presented an overview of the use of stainless steels for biomedical purposes.

Cast stainless steels have been used as implant materials (Ref 33), though their use has declined in recent years. There is one ASTM standard for cast stainless steel (F 745). The composition of this alloy is similar to the 316L composition given in F 138 (see Table 2) except that the %C is higher (0.06% max), as is %P (0.045% max),

%Si (1.0% max), and %S (0.030% max). Also, the %Ni and %Mo ranges differ, being 11.00 to 14.00% and 2.00 to 3.00%, respectively, in the F 745 alloy. No values for nitrogen and copper are given in F 745. Most importantly, the minimum chromium and molybdenum composition index for pitting and crevice-corrosion resistance is not specified in ASTM F 745. The implant-grade stainless steels are the easiest to machine of the three alloy systems used to form medical devices. These biomaterials are often used in a cold-worked condition. Micrographs of typical annealed and cold-worked 316L stainless steel are shown in Fig. 3. Many deformation twins are visible for the cold-worked alloy (Fig. 3b). The homogeneous austenite microstructure produced before cold working can be obtained by heating in the 1050 to 1100 °C (1920 to 2010 °F) range followed by rapid cooling to avoid precipitation of carbides (Ref 34). Note

that 316L and the F 1314 wrought nitrogen-strengthened steel have stringent restrictions on carbon content to minimize the possibility of sensitization. The mass density of stainless steels is roughly 7.9 g/cm³, and its Young's modulus is about 186 GPa (27×10⁶ psi) (Ref 20).

As previously discussed, of the three alloy systems used for orthopedic implants, the stainless steels are the least corrosion resistant under *in vivo* conditions (Ref 34). Sometimes electropolishing is used to improve corrosion resistance. Due to the possibility of ion release, concerns have been raised over the years about the systemic consequences of the nickel in stainless steel, because this element is the one most often implicated in metal-induced hypersensitivity reactions (Ref 20). Though only about 5% of the patient population experiences metal sensitivity due to implants, more than 90% of such cases involve nickel (Ref 35). Such concerns have spurred the development of high-chromium, high-manganese stainless steels. The manganese content prevents formation of martensite and allows much more nitrogen to be soluble in the lattice (Ref 31). The high nitrogen content strengthens the steel by formation of carbonitrides. Since nitrogen is also a potent γ stabilizer, the steel remains austenitic (and thus quite corrosion resistant), even while it is basically nickel-free (Ref 20). Recently, one such low-nickel stainless steel composition has been granted an ASTM standard (ASTM F 2229 as listed in Table 2).

The mechanical properties for the strongest conditions specified in the ASTM standards for the implant-quality stainless steels (that also give requirements for ultimate tensile strength, yield strength, and elongation values) are provided in Table 3. Some of these standards have mechanical property specifications for other conditions, and alloys in other conditions may be used by agreement between the alloy supplier and implant manufacturer.

Cobalt-Base Alloys

Cobalt has a high-temperature face-centered cubic (fcc) form (α) and a hexagonal close-packed (hcp) lower-temperature form (ϵ). The equilibrium transition temperature is 450 °C (840 °F), though in commercial alloys both forms may be present (Ref 34). The first cobalt-base alloy used for surgical implants was a Co-Cr-Mo casting alloy, originally known as Vitalium (Ref 33). The chemical composition of this alloy is in line with ASTM F 75. Since then, however, a number of alloys based on the Co-Cr alloy system have been introduced for wrought materials and forgings. These newer alloys have significant amounts of nickel, tungsten, and/or iron (and in one case no molybdenum). Table 4 shows the chemical composition of these biomaterials. ASTM F 75 is a casting alloy; ASTM standards F 799 and F 961 cover alloy forgings, and the rest of the alloys in the table are wrought materials. Certain of these alloys derive from

the Haynes Stellite (HS) alloys (Ref 36). ASTM F 75 is the analog of HS-21, and F 90 is the analog of HS-25. Pruitt and Hanslits (Ref 37) provide a general overview of cobalt-base alloy systems.

A range of mechanical property values can be developed in cobalt-base alloys depending on the alloy content and thermomechanical treatment. Alloying elements can provide both solution hardening (e.g., molybdenum and tungsten) and development of second phases (carbides, for example) that strengthen the base material through grain-boundary stabilization and dispersion strengthening (Ref 34). Large agglomeration of carbide phases will reduce fatigue life, however (Ref 34). The mechanical properties for the strongest conditions specified for the implant-quality alloys, which give ultimate tensile strength, yield strength, and elongation values, are provided in Table 5. For conditions

where the strength values are the same, the specification for the most ductile condition is listed in the table. The ASTM standards mentioned have mechanical property specifications for other working conditions and heat treatments.

ASTM F 75 and F 90 materials are generally rather coarse grained, and grains up to 3 mm diameter have been reported (Ref 36). The grain size for the thermomechanically processed F 799 material is much smaller (Ref 9). Typical microstructures of these materials are shown in Fig. 4 to 6. These alloys are generally single-phased (Ref 9), though in F 75 both α and ϵ can be present (Ref 34). Hot isostatic pressing of material with the F 75 composition will produce a fine-grain structure with finely dispersed carbides that has improved mechanical properties (Ref 34). The mechanical properties of ASTM F 90 are improved by deformation and twinning (Ref 34). The cobalt-base alloy described

by ASTM F 562 (also known as MP35N or Protosul-10) is a multiphased, high-nickel-content material and is stronger than the alloys mentioned previously. A high nickel content tends to stabilize the fcc α phase (Ref 34), which increases ductility in the alloy systems specified by ASTM F 90, ASTM F 562, and ASTM F 563. MP35N is strengthened by phase transformations induced by plastic deformation and by aging treatments leading to precipitation of Co_3Mo (Ref 34). Young's modulus for the ASTM F 75 and ASTM F 799 alloys is 195 GPa (28×10^6 psi), while for the alloy described by ASTM F 90, the value is 210 GPa (30×10^6 psi) (Ref 33).

Titanium-Base Alloy Systems

Titanium undergoes an allotropic transformation at 883 °C (1621 °F). The high-temperature phase (β) is body-centered cubic (bcc), while the lower-temperature phase (α) has an hcp crystal structure. For titanium alloys, depending on the alloying elements present and the thermomechanical treatment, one or the other (or both) of these phases will be found at room temperature. Titanium alloys are therefore classified as α alloys, β alloys, or α/β depending on the phases present in the microstructure. Near- α alloys are those that do contain a small amount of retained β , but not an amount that is sufficient to allow the material to be heat treated. For many years the only titanium-base materials used to make implants were commercially pure titanium (CPTi) and Ti-6Al-4V ELI. Biocompatibility concerns have been raised about the vanadium content (Ref 9); however, in recent years, titanium alloys containing lesser proportions of vanadium, and in some cases aluminum, have been developed for implant use. These newer alloys contain various other elements (namely niobium, molybdenum, zirconium, and iron) as well. The chemical compositions of the alloys for which ASTM standards have been formulated are shown in Table 6. The materials listed in the table are wrought alloys.

The alloying elements are classified according to whether they promote stability of the α phase (α stabilizers) or the β phase (β stabilizers) (Ref 34). The main α stabilizers found in implant materials are aluminum and the interstitial elements oxygen, nitrogen, and carbon. The main β stabilizing elements in implants are vanadium, molybdenum, niobium, and tantalum. The materials found in Table 6 represent different titanium alloy classes. For example, F 136

and F 1472 are α/β alloys, while F 2146 is a near- α alloy. Commercially pure titanium (ASTM F 67 and F 1341) is classified according to four different grades depending on the maximum amounts of iron and interstitial elements (oxygen, nitrogen, carbon, and hydrogen) that the material may contain, as given in Table 7. As the oxygen concentration increases from grades 1 to 4, the strength of the material increases (Ref 9).

The two Ti-6Al-4V alloys, ASTM F 136 (the ELI grade) and ASTM F 1472, also differ mainly in regard to the amount of interstitial impurity elements that are permitted, as shown in Table 8. Limits are placed on these elements since interstitials tend to have an embrittling effect on titanium-base materials. This is particularly true in the case of hydrogen (Ref 14). Commercially pure titanium in the annealed condition has an equiaxed microstructure, as shown in Fig. 7. Microstructures of other titanium-base implant alloys are shown in Fig. 8 and 9.

The mechanical properties for the strongest conditions specified for the implant-quality alloys, which also give requirements for ultimate tensile strength, yield strength, and elongation values, are provided in Table 9. Commercially pure titanium can be strengthened by work hardening (Ref 9) and, especially the grade 4 material, is sometimes used in this condition when extra strength is required. The other materials are usually, but not always, used in an annealed condition. The specified mechanical properties do, however, depend on diameter or thickness. For conditions where the strength values are the same, the specification for the most ductile condition is listed in the table. The original ASTM standards have mechanical property specifications for other sizes, working conditions, and heat treatments. The strength and

lighter in weight (Ref 34). Also, Young's modulus of titanium alloys are approximately half that of cobalt-base alloys and stainless steels.

Some THR femoral components and knee implants are made from cast titanium (Ref 38). A shape-memory alloy, Nitinol, is used in various dental applications (braces, for example) (Ref 34). This material is based on the Ni-Ti binary alloy containing 54.5 to 57.0% Ni, and the shape memory is based on formation of a martensitic phase and the reverse transformation. The desired final shape of the material is set at a temperature above the martensite start temperature (M_s). The material is then deformed to its temporary shape below the reverse transformation temperature (A_s). Upon subsequent heating above the A_s , the original shape is restored (Ref 34). For pure TiNi, the transformation temperatures are too high ($A_s = 165.6^\circ\text{C}$, or 330.1°F) for direct use in the oral cavity, but alloying with TiCo ($A_s = -237.2^\circ\text{C}$, or -395°F) can provide a practical dental material (Ref 34). Recently an ASTM standard has been developed (F 2063) that provides guidelines for the material quality of Nitinol used for fabrication of surgical implants.

Porous and Porous-Coated Materials

Over the last several years, bulk porous metal materials with interconnecting porosity have been developed. The two metals that have been used are titanium and tantalum. Porous tantalum has been used for a variety of applications, including the backing on acetabular components of hip prostheses, spinal implants, bone struts, and bridging material, to guide and support bone growth. There are a number of research publications regarding the mechanical properties and histological evaluation of implants made from this material (Ref 39–41). Even more recently, a bulk titanium porous material has been described (Ref 42). The porous titanium foam does not have completely interconnecting porosity, and, therefore, unlike the tantalum foam, will not allow bone to grow through the entire mass of the implant. Porous cobalt-base alloys are also used for implants. Andersen (Ref 43) has presented an overview of the use of powder-metallurgy processes in medical and dental applications.

Porous coatings are often used on portions of permanent implants (such as THRs) so that when tissue (usually bone) grows into the pores, a strong fixation between the artificial biomaterial and the natural tissue results. Though this approach makes good sense from a biomechanical point of view, from the standpoint of materials science, there are some potential concerns to consider. First of all, since the surface area actually exposed to contact with tissue fluids is much higher for porous-coated implants than for those with smooth surfaces, there is the possibility that a greater amount of corrosion products will be released from porous-coated materials, which potentially could heighten biocompatibility complications. Secondly, the irregular topography of porous-coated surfaces, whether formed by sintering of spherical powders, plasma spraying (see below), or sintering together of wire mesh, can conceivably represent stress concentrations that, particularly in notch-sensitive materials, could serve as focal points for crack nucleation. Thirdly, the processing techniques used to produce sintered porous layers can adversely affect the fatigue strength of the alloys used to produce porous-coated implants (see below).

Despite such concerns, the use of porous-coated layers on some portions of surfaces employed in total joint replacements has proliferated since the 1970s and has reached the point where ASTM standards have been developed for certain types of porous materials. Considering Co-Cr base materials, the alloy governed by ASTM standard F 799 can also be prepared by powder-metallurgy processes to form porous-coated layers on implants (Ref 33). ASTM standard F 1377 provides guidelines for the use of the F 75 alloy composition for orthopedic implant porous coatings. Standards have also been adopted for Ti-6Al-4V powder for use in making porous coatings (ASTM F 1580) and for α/β alloy forgings (ASTM F 620). Besides sintering, porous plasma sprayed titanium alloy layers can also be used to make implants (Ref 44).

Fraker points out various metallurgical pitfalls that can be associated with such materials (Ref 34). For example, sintering of Ti-6Al-4V should not be performed above the β transus, as this will adversely affect the fatigue behavior of the

material. One fabrication problem for porous-coated Co-Cr-Mo implant materials is that care must be taken during the sintering process and subsequent cooling, otherwise carbides can form that lower the tensile strength and ductility of the material. ASTM F 1537 grade 3 (Table 4) was developed to minimize the loss in properties that occurs during sintering.

Amalgam

Dental amalgam is not one material, but actually is a rather complex family of materials (see the article “Corrosion and Tarnish of Dental Alloys” in this Volume). Amalgam restorations are made by reacting liquid mercury and a solid alloy powder (usually termed amalgam alloy) in approximately equal proportions by weight (Ref 45). The amalgamation reaction produces a solid, but low-melting-point alloy. Invariably, the powder will contain phases based on the silver-tin binary system. Present in various amounts, depending on how the powder is prepared, these are an intermetallic compound Ag_3Sn (known as the γ phase), which forms by a peritectic reaction involving the liquid and a more silver-rich phase (β), and β that is retained at room temperature (Ref 46). Amalgam alloy containing only silver and tin as major alloying elements is rare. Modern amalgam alloy also contains relatively high concentrations of copper ($>12\%$). In the high-copper amalgam, the powder will be composed of a Ag-Sn-Cu ternary (high-copper single composition) or silver-copper eutectic alloy particles in addition to particles of a silver-tin alloy (high-copper admixed). In the first case, where there are not substantial quantities of copper, the amalgamation reaction can be represented as (Ref 46):

where the products $\gamma_1 + \gamma_2$ are also intermetallic compounds Ag_2Hg_3 and Sn_{7-8}Hg , respectively. In the second case, the reaction involved can be represented as follows, where the reactants are on the left side of the reaction arrow and the final product is shown on the right side of the reaction arrow:

where η is yet another intermetallic compound, Cu_6Sn_5 (Ref 46). The chemical composition range of amalgam alloy has been reported by Craig (Ref 47) as:

Element	Composition, wt%
Silver (Ag)	40–74
Tin (Sn)	25–30
Copper (Cu)	2–30
Zinc (Zn)	0–2
Mercury (Hg)	0–3

From the previous discussion, it can be seen that dental amalgam is a complicated, multiphased biomaterial. Micrographs of amalgam microstructures are shown in Fig. 10.

Though over the years amalgam has probably been the single most widely used biomaterial, a number of clinical problems have become evident related to the durability of the material in the oral environment that can require removal of the material. These include secondary caries, untoward corrosion and tarnish, “ditched” or fractured margins, creep, and gross fracture of the material (Ref 46). Factors that, from an engineering point of view, are related to amalgam deterioration in the oral cavity are thus corrosion resistance and resistance to applied mechanical forces.

Polarization curves of amalgam measured in an artificial saliva do show a passive region (Ref 19). The range of potential where passive film stability exists is much more restricted than is the case with the orthopedic alloys, however, and the passive corrosion current density is much higher for amalgam. The γ_2 phase, Sn_{7-8}Hg , which contains no noble metal content, is the phase most prone to corrosion in conventional (i.e., low copper) amalgam formulations. Similarly, for copper-bearing amalgams, it is the η phase, Cu_6Sn_5 , that is most prone to corrosion. Though, as pointed out previously, the environment in the oral cavity is not as aggressive as is the case in the internal milieu of the body, there are a number of corrosion mechanisms that can still be operative. For example, besides microgalvanic action occurring in the multiphase structure, macroscopic galvanic couples can develop as different types of restorative metals come into intermittent contact when patients bite down. Since amalgam may be in contact with both saliva and dentinal fluids with about a sevenfold difference in chloride concentration, a differential concentration cell may exist. Also, due to differences in oxygen concentration in solution at the interface between the amalgam and tooth structure, exacerbated by situations where there is margin breakdown and increased leakage, crevice-corrosion conditions can develop due to the differential aeration cell that forms. Because of the intrinsic toxicity of mercury, its presence in amalgam has been controversial in recent years, mainly because of its high vapor pressure and the fact that 65 to 85% of mercury vapor inhaled will remain in the body (Ref 46). There is a dose-response aspect to this issue, however. It has, for example, been estimated that the body burden of mercury that results from one meal per week of saltwater seafood exceeds that from the presence of 8 to 10 amalgam restorations in the oral cavity (Ref 46).

The presence of applied mechanical forces and possibly abrasive action from contact with foodstuffs could perhaps have adverse impact on passive films on amalgam due to fretting effects. Besides its problematic nature regarding corrosion, the mercury- and tin-containing phase is also the weakest phase in a mechanical sense, as demonstrated by microscopic observation in

crack initiation and propagation studies (Ref 47). According to one study, about one-quarter of clinical failures of amalgam are due to fracture of the material (Ref 48). Later in this article the role that fatigue may have in such failures is reviewed.

Issues Related to Simulation of the *in vivo* Environment, Service Conditions, and Data Interpretation

The key issues addressed in this section include:

- Frequency of dynamic loading
- Electrolyte chemistry
- Applicable loading modes
- Cracking mode superposition
- Surface area effects

Subsequent major sections in this article describe the fundamentals of CF and SCC, testing methodology, and test findings from laboratory, *in vivo*, and retrieval studies.

Frequency of Dynamic Loading. Since corrosion is an exposure time-dependent phenomenon, as would be intuitively expected, besides the number of loading cycles applied, the

(a)

(b)

Fig. 10 Typical microstructures of high-copper dental amalgam. (a) High-copper single composition. (b) High-copper admixed

frequency of loading, f , can exert a significant influence on the CF process. One reason for this is that crack propagation rates have a direct relation to mass transport kinetics and chemical reactions that foster embrittlement (Ref 15). Three types of behavior are defined in this regard (Ref 49). For purely time-dependent behavior, crack growth rate per cycle (da/dN) increases with decreasing frequency and is proportional to the time fraction of the load cycle where fatigue damage occurs, $1/(af)$. Thus, as frequency decreases a larger increment of crack extension occurs per loading cycle. The factor α comes into play since, due to effects such as crack closure, crack extension may not be occurring over all phases of the loading cycle. For example, in a symmetrical load cycle where CF cracking did not occur in the unloading portion of the cycle, α would equal 2. Time-dependent crack growth primarily occurs above the threshold stress intensity for SCC (K_{ISCC}) and can be modeled as a superposition of inert fatigue crack growth and SCC processes (Ref 15). For cycle-dependent behavior, the environment accelerates da/dN , but in a manner that is independent of f . For cycle/time-dependent behavior da/dN is proportional to $[1/(af)]^\beta$, where β is a constant whose value is approximately 0.5.

For fatigue testing in air or vacuum, where results do not appreciably differ with f , it is common to use a loading frequency as high as possible, usually 50 or 60 Hz or so. For CF, though, it is important to match the loading frequency in a test to the value that typifies the actual service environment, since extrapolation from high-frequency laboratory testing to a lower-frequency service environment is difficult. To simulate the environments that implants experience, usually a frequency of 1 Hz is used.

Electrolyte Chemistry. One of the most important aspects of any test to simulate electrochemical behavior under *in vivo* conditions is the environment to which the implant materials are exposed. There seems to be at least a partial lack of unanimity on the part of the implant corrosion research community on how to select the appropriate electrolyte to best simulate *in vivo* conditions, however. The total chloride content that should be present is often considered to be equivalent to 0.9 wt% NaCl. An electrolyte that is very commonly used is Ringer's solution, though the authors are aware of at least eight discrete formulations of this solution that have been published either by researchers involved in corrosion testing of implant alloys or in works related to various life sciences (Ref 50–57). The range of chemical composition for Ringer's solution found in these reports is shown in Table 10. As can be seen from the table, all of these solutions contain some NaCl and KCl, but the amounts differ and there are a variety of other ingredients (present usually in less abundance) that are found in some solutions, while absent in others. Details of the individual formulations for Ringer's solution can be found in the references themselves and in the

review article by Bundy (Ref 1). Tyrode's solution (Ref 58) and Hanks' solution (Ref 59) are other saline solutions that have been used as the electrolyte for corrosion tests with implant alloys.

Similarly, for investigating corrosion behavior of dental materials, a variety of electrolytes have been used for electrochemical testing. These range from simple NaCl solutions (Ref 60–64), as well as a variety of artificial saliva solutions containing additional inorganic and organic ions, low-molecular-weight organic substances, and proteins (Ref 65–70).

Virtually all *in vivo* solutions contain a significant concentration of proteins. Various studies (e.g., Ref 71–78) have been performed to determine how proteins affect the corrosion behavior of metallic implant and dental materials. The solutions used to simulate the action of proteins on corrosion processes generally contain mucin for testing of dental materials and albumin for orthopedic materials, since these are the most abundant proteins found in saliva and blood, respectively.

The influence of proteins on corrosion of implant and dental materials has been found to be complicated. Adsorbed proteins on biomaterial surfaces can form complexes with ions released due to corrosion, alter passivation characteristics, lead to development of active/passive cells because of inhomogeneous adsorption, and either increase, decrease, or leave the corrosion rate unchanged. Further information on this subject has been discussed by Bundy (Ref 1).

Though *in vivo* studies have been performed that suggest that proteins within the body could have some influence on SCC, no laboratory investigations have been conducted on this subject. Given the specificity of the chemical agents and crack tip conditions that can affect SCC, the presence in the body of tens of thousands of discrete proteins, as well as the fact that the chemical agent that makes an alloy vulnerable to SCC can be present at extremely low concentrations in the environment, the influence of proteins on the SCC process is an area that should be subjected to more systematic investigation in future studies.

Applicable Loading Modes. For CF or SCC testing the usual practice is to use a simple loading mode for the test, typically applied in tension or bending. It should be recognized, though, that this is an oversimplification when it comes to simulation of conditions that implants experience in service. The loads applied by the musculoskeletal system to an actual implant can be complex and multiaxial and can include tension, compression, bending, torsion, and mixed-mode situations in which a combination of these occur.

In situations where the applied loading is complex and the stress amplitude can be widely varying (a scenario that certainly characterizes the *in vivo* environment), the most commonly used method for estimating fatigue life due to this cumulative damage is the linear damage law

(Ref 79), which says that fatigue failure occurs when:

$$\Sigma(n_i/N_i) = 1 \quad (\text{Eq } 6)$$

where n_i is the number of cycles applied with stress amplitude σ_i , for which the mean number of cycles to failure is N_i .

For CF testing of implants, it is typical to apply uniaxial dynamic loading using a single sinusoidal waveform. However, the time course of loading of an implant over the gait cycle is more complex than this. More realistic waveforms to more closely simulate actual loading have been used in SEIR studies (Ref 2, 4, 80), but the only nonsingle sinusoidal waveform used in CF studies has been a square wave (Ref 81). Furthermore, periods of rest (that always characterize loading of implants) and loading that may change systematically over time due to processes such as shifting of the position of the implant, cracking of bone cement, and bone deterioration due to osteoporosis (Ref 36), may represent further complications. In terms of comparing laboratory simulations to *in vivo* conditions, though, these investigators assume that in the case of fatigue, when a fatigue striation pattern is observed in the laboratory that matches one observed *in vivo*, the inference can be drawn that the loading conditions were comparable. Such an approach is used in the aircraft industry.

Cracking Mode Superposition. Yet a further complication is that the actual crack propagation velocity observed V_{obs} can result from a superposition of crack growth increment contributions due to SCC, V_{SCC} , to the additional crack growth rate during cyclic loading that is due to the corrosive environment, V_{CF} , and the mechanical fatigue crack growth rate in air, V_{air} (Ref 31):

$$V_{\text{obs}} = V_{\text{SCC}} + V_{\text{CF}} + V_{\text{air}} \quad (\text{Eq } 7)$$

Surface Area Effects. Particularly for high-cycle CF experiments with smooth samples, it should be recognized that the CF process can be strongly influenced by surface damage resulting from electrochemical attack. As the surface area of the test specimen increases, therefore, it is possible that the measured number of cycles to failure will decrease. So, consideration should be given on how to scale the measured CF behavior of an implant material test specimen with one

Table 10 Range of chemical composition for components in Ringer's solution

Component	Concentration, g/L
NaCl	6.0–9.0
KCl	0.1–0.42
CaCl ₂	0–0.33
NaHCO ₃	0–2.4
NaH ₂ PO ₄	0–0.01

MgSO ₄ ·7H ₂ O	0–0.12
Na ₂ HPO ₄	0–0.07
NaH ₂ PO ₄ ·H ₂ O	0–0.07

surface area to that of a surgical implant device with a different surface area value.

Fundamentals of Fatigue and Corrosion Fatigue

Since most variables that affect metal fatigue also influence CF, both of these phenomena are discussed in this section. Fatigue failures have been studied by materials scientists for many decades. In a macroscopic sense, even a normally ductile material fails in a manner that is basically brittle under the action of fatigue loading. Fatigue failures involve repeated dynamic cyclic loading of an engineering component. In the low-cycle fatigue (LCF) regime, the durability of a smooth material subjected to cyclic mechanical loading can be expressed in terms of the Coffin-Manson equation (Ref 49):

$$\Delta \epsilon_p = \epsilon'_f (N_f)^{-c} \quad (\text{Eq 8})$$

where $\Delta \epsilon_p$ is the range of true axial plastic strain in a fatigue loading cycle, N_f is the number of loading cycles to failure, and ϵ'_f and c are material property parameters. When the number of cycles exceeds the transition fatigue life N_T , a smooth specimen will fail by high-cycle fatigue (HCF) according to the Basquin equation:

$$\Delta \sigma = \sigma'_f (N_f)^{-b} \quad (\text{Eq 9})$$

where N_f again refers to the number of cycles to failure, and σ'_f and b are material properties. The material properties in each of these equations depend on metallurgical, environmental, and time variables (Ref 49). The transition fatigue life is the number of load cycles when the magnitudes of the elastic and plastic strain ranges become equal. The LCF regime is generally when $N < 10^4$ (Ref 82). Since implanted biomaterials are almost exclusively designed for service lifetimes to be as high as possible, HCF fatigue phenomena are of primary concern for metallic surgical implants. When the stress amplitude is low so that the number of cycles to failure is relatively high, the conditions are such that there is sufficient elapsed time so the influence of environmental effects on failure becomes more prominent.

Description of Phenomena

In CF the material is damaged by the conjoint action of mechanical stresses and electrochemical attack. Generally speaking, the Coffin-Manson (Eq 8) and Basquin (Eq 9) laws apply to CF phenomena as well, though in electrochemical environments these laws may be characterized by multiple power law segments (Ref 49). Most importantly, this means that the endurance limit that can apply to fatigue tests in air or vacuum will be eliminated due to the action of the electrolyte. The premature failure that can result due to CF is shown in Fig. 11, which illustrates S - N curve behavior (applied stress versus number of cycles to failure) for 316L

in distilled/deionized water versus the same material in Ringer's solution. Also, the fatigue strength of a material in a corrosive environment will be less than that in air, so a material will fail at a fewer number of load cycles in an aqueous electrolyte when compared to inert conditions at the same load.

This behavior is commonly explained in terms of pitting-based crack initiation. Besides pitting, other causes of CF crack initiation include surface damage and minute flaws or hidden imperfections (Ref 34). However, since it is impossible to produce a totally defect-free material from a metallurgical point of view, standards that set quantitative limits for these defects have been established (for inclusion content, for example). The stresses involved in fatigue fracture are often substantially below the nominal yield strength of the material (Ref 83). This is particularly true for biomaterials in surgical implant applications, because when a material experiences yielding *in vivo*, in a functional sense it has already failed. This is a situation that implant designers go to great pains to avoid, but design is *always* limited by the anatomy and physiology of the patient.

Pohler (Ref 84) describes three forms of corrosion fatigue. The first type is pitting-based crack initiation, as mentioned previously. In the second type, fatigue crack initiation and propagation are enhanced by simultaneous electrochemical dissolution. In type 3 (the most common type for implants that meet quality-control standards), visible corrosion does not occur, but passive film destruction in the electrolyte is responsible for reducing fatigue life. With retrieved implants, though, fracture surfaces sometimes show secondary corrosion due to crevice corrosion or fretting in the implant fracture gap (Ref 11), which could be considered as a fourth form of CF.

Fatigue failure of a material occurs by a three-stage process. Stage I consists of crack initiation and initial propagation (Ref 85). Stage II consists of steady-state crack propagation, which can be identified on fractographic surfaces by characteristic surface features known as fatigue striations. Stage III represents ductile overload fracture that occurs when the ligament of intact material remaining after fatigue crack propaga-

tion is too small to withstand the applied stresses (which now exceed the tensile strength of the material).

Crack Initiation. In CF type I, which involves pitting-based crack initiation, no fatigue limit exists and corrosive attack is localized. Crack initiation kinetics are controlled by the rate at which pits nucleate and grow to a critical depth (Ref 86). The critical pit depth depends on the range of applied alternating stress. Other factors related to crack initiation include the presence of notches, manufacturing defects (as mentioned previously), and inhomogeneous strain distribution in the loaded structure (Ref 87).

For type III CF, the most common form in surgical implants, fatigue cracks can initiate without initial stress raisers or other flaws (Ref 11). Here, persistent slip steps are formed and the unprotected metal surface exposed as the slip steps breach the passive film will be attacked until repassivation occurs, since a microgalvanic cell is established between the freshly exposed metal and the adjacent material covered with an intact passive film. As these slip emergence and dissolution cycles proceed, a small, local notch can form (Ref 86). These slip bands created by fatigue can have the appearance of extrusions and intrusions at the surface (Ref 11). When these sharp notches reach a critical depth (which is a function of the applied dynamic stress range), a fatigue crack is initiated. For type III, crack initiation is controlled by the critical notch depth and repassivation kinetics (Ref 86). It has been suggested that there is a critical current density for repassivation below which this process cannot be sustained, in which case initiation is controlled by the processes that control it in air (Ref 88). This film rupture/repassivation process is similar to mechanisms thought to be responsible for SCC (see the section "Fundamentals of Stress-Corrosion Cracking" in this article), and Jones (Ref 89) has worked out a unifying explanatory theory for CF and SCC.

As much as 90% of the fatigue life can be taken up by the crack initiation process. Eventually, increasing quantities of multiple slip systems will become operative; precracks, short secondary cracks, and finally one or more major cracks will form, as shown in Fig. 12. A crack

Fig. 11 S - N curves for 316L stainless steel showing premature corrosion fatigue failure when immersed in Ringer's solution compared to deionized/distilled water (37 °C, or 98.6 °F)

Fig. 12 Persistent slip band formation during stage I fatigue of a retrieved 316L stainless steel implant

will then proceed through the cross section of the implant. The progression of events has been shown micrographically (Ref 11). The multiplicity of crack origins is particularly characteristic of a CF process (Ref 83).

In stage I, crack growth is a strong function of mean stress level and dependent on microstructure (Ref 90). The cracks tend to follow crystallographic planes, but may change direction at grain boundaries or other discontinuities (Ref 86). Stage I fracture surfaces are faceted, often giving the appearance of a brittle cleavage fracture (Ref 85). Stage I fatigue damage is more prevalent in HCF as opposed to LCF.

Crack Propagation. In stage II crack propagation, since a definite crack exists, the ability of the material to resist applied loads is governed by linear elastic fracture mechanics principles. Here, the stress-intensity factor K plays a dominant role. The stress-intensity factor K combines the influence of specimen geometry, loading, and crack size, and is a single parameter that describes the elastic stress field in the vicinity of the crack tip (Ref 91). In this case, both fatigue and CF cracks propagate according to the Paris equation:

$$da/dN = A(\Delta K)^m \quad (\text{Eq 10})$$

where a is the crack length, N is the number of loading cycles, da/dN is the average rate of fatigue crack growth, and A and m are material-dependent constants (independent of the specimen geometry). The exponent m has a value generally between 2 and 10 (Ref 15). The constant A is inversely proportional to the shear modulus of the material, the square of the yield strength, and the amount of plastic work required to advance the crack by unit area (Ref 92). Only tensile stresses are included in the ΔK range, since compressive stresses do not cause appreciable damage and plastic strain at the crack tip (Ref 49). In a vacuum, there will be a threshold stress intensity below which da/dN tends toward zero and cracks will not propagate. Here, the threshold stress-intensity range is often designated as ΔK_{th} and represents the point at which nonpropagating cracks become propagating under fatigue conditions (Ref 93). In a CF situation, however, cracks will continue to propagate at a slow rate even at quite low values of ΔK (Ref 49).

Stage II cracks usually propagate in a transgranular manner. Morphologically, the most characteristic microscopic signature of stage II is the presence of fatigue striations on the fracture surface. Examples are shown in Fig. 13. Each striation is caused by a single stress cycle, yet the stress during every cycle is not necessarily sufficient to result in crack propagation and the production of a striation (Ref 83). The striations are basically parallel to each other and perpendicular to the direction of crack propagation. Striations have a slight curvature to them, and the direction of crack propagation can be determined from this. The propagation direction is the direction proceeding from the concave to the

convex side of the striations. In stage II, secondary cracking may occur as well (Ref 9). A secondary crack occurs at a striation, and its plane lies oblique to the plane of the main crack.

The percentage of the fracture surface area involved in stage II crack propagation can exceed 90% (Ref 9). Macroscopically, there are characteristic features on a fracture surface that allow a fatigue process to be identified. These features are variously known as progression marks, beach marks, crack arrest marks, or clam shells (Ref 9, 83, 85). They are crescent-shaped markings that indicate successive positions where arrests occurred in the advancing crack front. An example is shown in Fig. 14(a). The fracture surface is generally smoother near the crack initiation point and rougher more remote

from it. The crack origin can be identified as the apparent focal point on the exterior surface of a part from where the beach marks appear to emanate. Characteristic chevron marks are shown in Fig. 14(b).

Stage III. In stage III the rate of crack propagation increases until the last ligament of remaining material is no longer able to bear the load, and the material then catastrophically fractures. In this regime, it is mainly static failure modes that predominate (Ref 83), that is, cleavage or dimple rupture (depending on whether the material fails in a brittle or ductile manner). Examples of brittle and ductile stage III fractures are shown in Fig. 15(a) and (b), respectively. Stage III failure depends on the microstructure of the material and the mean stress level (as opposed to the range of stress as is the case in stage II). The crack growth rate as a function of ΔK over the course of the fatigue life of a material for the three stages discussed is shown schematically in Fig. 16.

Factors Influencing Susceptibility to Corrosion Fatigue

A great many mechanical, electrochemical, metallurgical, processing, biological, and statistical variables and phenomena affect CF under *in vivo* conditions. In general, any factor that promotes pitting corrosion, allows an embrittling species to enter the metal lattice, promotes crack tip strain-hardening relief, and/or interferes with

slip reversal at the crack tip will promote crack growth and lower the CF life of a material (Ref 86). These variables and factors are discussed in this section.

Stress Raisers. For a structural discontinuity that acts as a stress raiser, for example, a hole, notch, or scratch, the degree of stress concentration can be quantified by the stress-concentration factor K_t , which is the ratio of the greatest stress that occurs in the vicinity of the stress raiser to the nominal stress (Ref 95). For cyclic loading, the maximum range of stress $\Delta\sigma_{\max}$ is experienced at the tip of the notch and is related to the stress-intensity range:

$$\Delta\sigma_{\max} = 2\Delta K / (\pi\rho)^{1/2} = \Delta\sigma K_t \quad (\text{Eq 11})$$

where ρ is the radius at the tip of the notch, and $\Delta\sigma$ is the range of applied nominal stress (Ref 96).

Notch Sensitivity. In fatigue testing of notched specimens, the fatigue notch factor K_f is defined as the ratio of the fatigue strength of a smooth, unnotched specimen to the fatigue strength of a notched specimen at an equivalent number of stress cycles. The fatigue notch sensitivity, q , is a measure that compares the stress-concentration factor and the fatigue notch factor. It is commonly defined as:

$$q = (K_f - 1) / (K_t - 1) \quad (\text{Eq 12})$$

The presence of a sharp notch will decrease the time required for a CF crack to initiate (Ref 49). For steels in a NaCl solution, the relation-

ship between the number of cycles required for crack initiation N_i and ρ is:

$$\Delta K / (\rho)^{1/2} = -m[\log(N_i)] + b \quad (\text{Eq 13})$$

where m and b are constants with positive values. The sharper the notch and the larger the range of stress intensity, the fewer will be the number of cycles required to initiate a fatigue crack. In design of surgical implants, notches and other stress raisers should be avoided if possible without sacrificing the efficacy of the device.

Contributory Mechanical/Chemical Phenomena. Because of the complexity of both the loading environment and the corrosion environment *in vivo*, there are a number of effects and overlapping and related phenomena that can influence CF and SCC. The influence of pitting corrosion on crack initiation for CF has been discussed previously. Pitting has a similar effect on the SCC process. At this point it should be noted that prior to the mid to late 1980s, the composition of implant-grade 316L was substantially different than for the material that is used today to manufacture implants. This change in composition has had a significant effect on the properties of the alloy, especially corrosion resistance. This point should be kept in mind as the literature that has developed over time regarding CF and SCC is reviewed in this article. To consider another example where multiple phenomena are involved in the process of failure for stainless steel (not the 316L of the current composition as specified by ASTM F 138/139), instances are known where fretting and fretting

corrosion were involved in the fatigue crack initiation process (Ref 97). A similar process has been hypothesized by Jones et al. (Ref 58) for SCC in implants, and this is the main concern in regard to SCC of airframe components (Ref 98). Pohler (Ref 11) points out that, in rare cases, fatigue attack can be combined with stress corrosion of 316L to cause implant failure.

Any process that can breach the integrity of the passive film on an implant surface (wear, for example) can be suspected of facilitating crack initiation due to the fostering of pit initiation. The influences of the environment (electrolyte composition, temperature, pH, viscosity, conductivity, etc.), electrode potential, biological activity, and mechanical strain (insofar as it creates clean, nonpassivated metal surface) on CF can often be attributed to mass transport and electrochemical reactions that occur within pits, crevices, and cracks (Ref 49).

There is a relationship between CF and SCC for purely time-dependent fatigue crack propagation (see the section above titled "Frequency of Dynamic Loading"). Here, CF and SCC have the same operative mechanism (Ref 49) and are influenced by the same variables, so that the crack propagation velocity is the superposition of the rates for the two processes individually (Ref 99).

Microstructural Features, Processing Variables, Surface Finishing Features, and Metallurgical Defects Related to CF. A number of surface or internal discontinuities are known to act as nuclei for fatigue fractures and SCC failure by either increasing local stresses or adverse reaction with the service environment

(a)

(b)

Fig. 15 Micrographs characteristic of stage III fatigue failures. (a) Ti-6Al-7Nb alloy that failed by cleavage-type fracture. (b) Ti-6Al-4V ELI alloy that failed by ductile overload fracture

Fig. 16 Fatigue crack growth rate as a function of stress-intensity range. Source: Ref 94

(Ref 86). Such features include cold shuts, seams, laps, porosity, prior cracks, inclusions (oxides, sulfides, and silicates), segregation, and unfavorable flow of grains in forgings. These can act as sites for fracture initiation, causing fractures to start earlier or at lower loads than would be the case in their absence.

Sulfide inclusions can promote corrosion by acting as catalysts for the cathodic reaction (Ref 100). Large inclusions or second-phase particles are also known to affect the local rate of crack propagation (Ref 86). When a fatigue crack approaches such a discontinuity, it is temporarily slowed down if the particle remains intact and will accelerate in the local area if the particle is cleaved. Any single defect (inclusion or otherwise), even if present, should not automatically be singled out as the sole cause of a fracture, however, without first performing a thorough failure analysis to consider other possible causes and contributory factors that could have led to a fracture anyway, without the discontinuity being present. In part because of the adverse effect of inclusions on the fatigue process, the ASTM standards governing surgical implant metals have provisions limiting inclusion content.

Processing steps, such as working, quenching, grinding, polishing, shot peening, machining, and so forth, can produce surface residual stresses in metallic materials (Ref 101). These will add to the applied stresses. Since fatigue failures generally originate at the point of highest tensile stress, residual stress can be beneficial for increasing fatigue life if the stresses are compressive, but residual tensile stresses will generally serve to reduce fatigue life (Ref 102).

The CF behavior of 316L stainless steel has been shown to be sensitive to a number of surface condition and metallurgical variables. Sensitization of austenitic stainless steels, besides making the alloy more prone to intergranular corrosion, has an adverse impact on CF (Ref 103). Methods to avoid sensitization through modification of alloy composition and appropriate heat treatment have been described (Ref 104, 105). Yu et al. (Ref 106) have shown that the CF life of 316L can be increased by almost a factor of 3 by using a finely polished surface as opposed to a coarsely polished one. Laser shock peening has been shown to increase the fatigue life of stainless steel bone screws when the power level used is optimized (Ref 107). For surgical implants, 316L is very often used in a cold-worked condition. The purpose of this treatment is mainly to increase the yield strength, but cold work has also been shown to improve the fatigue properties of 316 stainless steel, as well, by lowering the da/dN value at a given ΔK (Ref 31). Brunner and Simpson (Ref 108) also considered the effect of surface finish and pointed out the possibility of a loss of fatigue strength due to implant contouring. Using a testing device designed for wire testing, Coquillet et al. (Ref 109) investigated the fatigue behavior of austenitic stainless steel orthodontic wires, as influ-

enced by cold work. They measured the ratio of the fatigue limit to σ_{UTS} to be roughly in the 0.25 to 0.50 range depending on the degree of cold work. Up to 12% cold work the ratio increased, but after that it declined (and could be even less than for the 0% cold-work condition). Surface defects were also seen to adversely influence fatigue resistance. Hochman and Taussig (Ref 110) have shown that a 2 h low-temperature stress-relief annealing heat treatment at 370 to 425 °C (700 to 800 °F) improves the fatigue resistance of 316L. Davis (Ref 111) points out, however, that the benefits of such a procedure should be weighed against possible difficulties associated with the potential for sensitization.

For Ti-6Al-4V, Yu et al. (Ref 106) studied the CF resistance of samples subjected to different heat treatments. They found that the alloy most resistant to CF was the one that had the finest prior- β grain size. The cracks were observed to propagate along the boundaries between the acicular α and β phases. Ion implantation had been proposed as a means to enhance fatigue strength of implant alloys (Ref 112), and Yu et al. (Ref 106) also determined that an ion-implantation treatment in which nitrogen was implanted in the surface improved both CF resistance and corrosion resistance of Ti-6Al-4V. Wang and Müller (Ref 113) have investigated the fatigue behavior of various titanium-base alloys. They found that the exponent m in the Paris equation changes at a stress-intensity transition point when either the monotonic or cyclic plastic zone size becomes comparable to a key microstructural feature.

In near- α and α/β titanium alloys, the three types of microstructures that can be developed are fully lamellar, fully equiaxed, and duplex (primary α in a lamellar matrix) (Ref 114). For equiaxed microstructures, the grain size and cyclic plastic zone size controls the fatigue behavior. For lamellar structures, the width of lamellae is the controlling microstructural variable, and the monotonic and cyclic plastic zone sizes, respectively, determine the transition point in coarse and fine lamellar structures. Finer structures have improved fatigue resistance (Ref 114). Fatigue cracks generally nucleate in the α phase (Ref 114). For equiaxed microstructures at high ΔK , cracks propagate in a linear, microstructurally insensitive manner, while a tortuous crack path will be found in lamellar structures when the monotonic plastic zone is contained in a single prior- β grain or lamella colony. Other factors found to influence fatigue behavior of near- α and α/β alloys are alpha grain size, colony size of lamellar microconstituents, degree of age hardening, and oxygen content (Ref 114). In duplex structures the volume of α has a strong effect. Though fatigue crack growth in titanium alloys is generally thought to be slower in coarse-grained microstructures, this is only true for long cracks at low values of R (<0.3) (Ref 114, 115). The R ratio is discussed in the section "Corrosion Fatigue Testing Methodology" in this article. When the fatigue resistance of lamellar and

equiaxed structures are compared for Ti-6Al-4V, fatigue crack growth rates are much higher for the fine microstructure characteristic of the mill-annealed condition compared to the coarse lamellar structure of the β -annealed condition, particularly when ΔK is low (Ref 115). Mill-annealed microstructures consist of nearly equiaxed α grains with fine β -phase regions, while β -transformed structures have long α lamellae with a thin β -phase boundary (Ref 36). For duplex structures, crack velocity lies between these two extremes.

Influence of Composition. In 316L stainless steel, CF cracks can be initiated due to pitting processes. Yu et al. (Ref 106) showed that doubling the molybdenum content of 316L stainless steel (normally 3 wt%, Ref 34) substantially improved the CF resistance of the alloy, due to the enhanced resistance to pitting conveyed by the increased concentration of molybdenum. The nitrogen level in 316L is restricted to be less than 0.1 wt% (Ref 116). Vogt (Ref 117), however, has shown increasing the nitrogen concentration up to 0.25 wt% increases LCF resistance.

Kalantary et al. (Ref 118) have studied how temperature affects the LCF behavior of 316L stainless steel. They find a minimum in the LCF life between 40 and 70 °C (105 and 160 °F), where the fatigue life is only half that at 20 or 100 °C (70 or 212 °F), an effect that is related to the diffusional mobility of interstitial carbon and nitrogen atoms in the vicinity of an advancing crack tip and how these atoms interact with dislocations present in this vicinity. This finding may be of interest for implant alloys where the service temperature is 37 °C (98.6 °F).

Influence of Surgical Implantation. In the process of implanting a biomedical device, surgeons inevitably must bring surgical instruments in contact with the surface of the biomaterial, as well as applying (sometimes considerable) mechanical force to the device. Use of these tools may cause a breach in passive film integrity on the implant, lead to plastic deformation, and/or create residual stresses. All of these factors can have a negative impact on CF resistance, as described previously. The material damage caused by implantation may be accidentally inflicted, as when a surgical instrument scrapes the implant surface and scratches the passive film, or due to intentional action such as contouring the device (plastically deforming it to alter its shape) so that it will fit and conform to anatomical constraints. Plastic deformation may also result from accidental surgical mistakes, such as when bone screws are overtightened and deformed upon insertion, which can lead to enhanced fatigue fracture as well as fracture of the screw during explantation (Ref 9). Because of differences in torsional work-hardening characteristics, overtightening of screws is more likely for titanium than for stainless steel (Ref 20), though with increased experience with using titanium, the surgeon can learn how to compensate for this effect.

Statistical Considerations. In a stress-controlled fatigue test, the stress level is generally the independent variable. Fatigue failure is a statistical process, and so N_f is a random variable. The statistical distributions that have been found to be most valuable for estimating fatigue life for a given stress level are the log-normal distribution and the Weibull distribution (Ref 119, 120). The Weibull distribution offers the advantages that it provides a more conservative estimate on the low side of fatigue life probability and that it was originally developed to model "weak-link" behavior in fatigue applications. It provides a good description of extreme value problems such as estimating the number of cycles to the first failure by CF, the depth of the deepest pit on a corrosion specimen, the time required for the first SCC failure, the time to the first leak in a length of pipe, and so forth (Ref 121). The Weibull distribution can be expressed as:

$$\ln[-\ln\{1 - F(x)\}] = c \ln(x - a) - c \ln(1/b) \quad (\text{Eq 14})$$

where $F(x)$ is the cumulative probability of the occurrence of an event, a is a minimum threshold value (that is greater than zero) for x such that below the threshold value there is 0 probability that the event will occur, b is a scaling parameter, and c is a shape factor (Ref 120).

Corrosion Fatigue Testing Methodology

Corrosion fatigue tests can be classified as to whether the main process occurring over the test is crack initiation or propagation. In crack initiation testing, the specimen generally has a smooth surface, and either axial or bending loads are applied. Thus the sample will be subjected to tensile and compressive stresses. Crack propagation tests use a fracture mechanics approach in which the growth of preexisting cracks due to cyclic loading is monitored. A fundamental parameter used to describe a fatigue process in smooth specimens is the stress ratio R , defined as:

$$R = \sigma_{\min} / \sigma_{\max} \quad (\text{Eq 15})$$

where σ_{\max} and σ_{\min} are the maximum and minimum stresses applied over the loading cycle, respectively. When the fracture mechanics approach is used, R equals K_{\max}/K_{\min} . When a loading cycle is fully reversed and the greatest magnitude of compressive stress equals the maximum tensile stress, $R = -1$. When a material is cycled from 0 load up to a maximum tensile stress and back, $R = 0$. The mean stress, σ_m :

$$\sigma_m = (\sigma_{\max} + \sigma_{\min})/2 \quad (\text{Eq 16})$$

has a large influence on fatigue behavior. For a given fatigue life, characterized by the number of cycles to failure N_f , the permissible stress

amplitude σ_a is strongly dependent on σ_m . The stress amplitude is defined as half of the stress range:

$$\sigma_a = (\sigma_{\max} - \sigma_{\min})/2 \quad (\text{Eq 17})$$

Three relationships (Ref 82) have been used to describe the decrease in fatigue strength with increased mean stress:

$$\sigma_a = \sigma_{fs} [1 - (\sigma_m / \sigma_{uts})] \quad (\text{Eq 18})$$

$$\sigma_a = \sigma_{fs} [1 - (\sigma_m / \sigma_{uts})^2] \quad (\text{Eq 19})$$

$$\sigma_a = \sigma_{fs} [1 - (\sigma_m / \sigma_y)] \quad (\text{Eq 20})$$

where σ_{fs} is the fatigue strength when $R = -1$ ($\sigma_m = 0$), σ_y is the yield strength, and σ_{uts} is the ultimate tensile strength. Equations 18 to 20 are known as the modified Goodman law, Gerber's law, and Soderberg's law, respectively.

The stress ratio can also have an effect on crack propagation when a fracture mechanics approach is used. For example, fatigue crack growth rates in austenitic stainless steels increase as R increases (Ref 31). To account for this effect, an effective stress-intensity factor K_{eff} is used in the Paris equation instead of ΔK to determine the rate of fatigue crack growth:

$$da/dN = A(K_{\text{eff}})^m \quad (\text{Eq 21})$$

where K_{eff} is defined in terms of R :

$$K_{\text{eff}} = K_{\max}(1 - R)^n \quad (\text{Eq 22})$$

where n is an empirically determined exponent. Other empirical approaches to account for this effect are also considered in Ref 31.

Fatigue Sample Morphology. Tests with smooth and notched specimens may be used to investigate the initiation of cracks. Since fatigue is a surface-sensitive property, particular care should be taken to standardize the machining of test specimens and the preparation of their surfaces (Ref 82). Various types of loading modes are used to apply stresses to fatigue specimens. When these are conducted, either the applied stress or the applied strain is controlled. For axial or direct stress specimens, the stress or strain is uniform across the cross section. In a rotating bending beam test, a specimen with a circular cross section is rotated while the sample is subjected to dead-weight loading. Either four-point bending or cantilever bending can be implemented with this arrangement. Fatigue can also be investigated with plate specimens subjected to reverse cantilever bending. This is a plane bending test. Three-point bending fatigue tests are also conducted. Another commonly used loading mode for fatigue testing is alternating torsion. Finally, since service conditions often involve multiple loading modes, multiaxial loading is sometimes used to conduct fatigue tests. Recently, a tension-tension standard method for CF testing has been established by ASTM for evaluation of metals used for biomedical implants (ASTM F 1801).

A variety of testing machines are used to conduct fatigue experiments, including those of

servohydraulic, electromechanical, and electromagnetic design (Ref 121). Additionally, a wide variety of specimen shapes and sizes are employed for fatigue testing. Since fatigue is a surface-area-sensitive phenomenon, size effects will affect testing results. Scaling for direct prediction of fatigue life of a complex part in service from tests on laboratory samples is generally not feasible (Ref 82).

Corrosion fatigue tests are patterned after the testing techniques used for fatigue testing in air or vacuum, but have additional concerns regarding the presence of the corrosive electrolyte. For example, galvanic coupling with the grips of the testing machine must be avoided and care should be taken to eliminate crevice-corrosion problems at the entry points of the specimen into the environmental cell. Precautions must also be taken to maintain a constant solution temperature, and the purity and constancy of the chemical composition of the electrolyte must be maintained. The potential of the specimen should be monitored and, for some testing purposes, potentiostatically controlled (Ref 49), although monitoring and/or control of these parameters are not required in ASTM F 1801. These conditions require that attention be paid to the electrical isolation of the test specimen from the loading mechanism. Additionally, IR (voltage) drop effects should be accounted for, and measurement of specimen displacement and load can be hindered by the presence of the electrolyte.

The fracture mechanics approach has been mentioned previously. This technique is based on the principle of similitude, that is, the notion that K (the stress-intensity factor) establishes the near-crack-tip driving forces for crack propagation and can be used to describe crack growth for specimens with different geometries and applied loads (Ref 121). The stress intensity is defined as (Ref 122):

$$K = \sigma a(\pi a)^{1/2} \quad (\text{Eq 23})$$

where σ is the nominal applied stress, a is a characteristic dimension of the flaw size, and α is a factor (determined from linear elastic stress analysis for the specific geometry of interest) that is a function of a/W , where W is the width of the specimen.

Structures used to be designed according to "safe-life" principles in which a crack-free service life was required (Ref 123). Fracture mechanics is a design tool used for crack-tolerant structures (Ref 124), and its basis is "fail-safe" design (Ref 123). This approach came into widespread use along with the introduction of high-strength materials in engineering applications. The basic notion behind fracture mechanics is that the presence of a crack does not signal immediate failure of a structural component. This will not occur in a CF process until the crack reaches a critical size. The purpose of CF testing based on fracture mechanics is to determine the rates at which such subcritical cracks grow before reaching the critical length (Ref 15).

However, such tests do not evaluate the crack initiation process itself. The critical value of the stress intensity K_{IC} (also known as the plane strain fracture toughness) is a material property (independent of the specimen geometry). Testing procedures are generally patterned after those described in ASTM standard E 647 (which contains an appendix related to CF in marine environments), though it should be noted that the principle of similitude is a mechanical one and it may not completely describe processes where the driving forces for crack growth involve interaction of both chemical and mechanical phenomena (Ref 15).

This approach separates the crack propagation process from the initiation process through use of a preexisting subcritically sized crack in the test specimen. The method described previously is known as linear elastic fracture mechanics (LEFM). When the crack tip is not sharp and there is significant crack tip plasticity (known as blunting), elastic-plastic fracture mechanics (EPFM) is usually used to characterize the fracture process. For EPFM, additional techniques are employed: crack tip opening displacement, J -integral, and R -curve methods (Ref 125, 126).

Testing based on fracture mechanics often involves situations where the test specimen is under plane strain. This condition puts limits on the thickness B of specimens that can be used. When B is equal to or exceeds $2.5(K_{IC}/\sigma_y)^2$, plane strain conditions apply; when $B \leq (K_{IC}/\sigma_y)^2/\pi$, plane stress conditions exist; and for B values between these limits, mixed conditions exist (Ref 124, 127). A variety of test geometries can be used for CF testing. These include compact tension, center-cracked tension, single-edge-crack bending, single- and double-edge-crack tension, surface-crack tension, and disk-shaped compact specimens (Ref 49, 128). Crack lengths are most commonly monitored with compliance, electrical potential difference, or optical methods (Ref 15, 49).

Findings from Corrosion Fatigue Laboratory Testing

Stainless Steels. A number of researchers have investigated the CF behavior of implant-quality stainless steels focusing on 316L. Comparative results of these tests are shown in Table 11, which gives fatigue data taken in air and in Ringer's solution using smooth specimens. Because there is no clear endurance limit observed in saline solution, the fatigue strength at 10^6 load cycles, σ_{fs} , determined from the S - N curve, is given in the table.

The table clearly shows that 316L can be vulnerable to corrosion fatigue, with a reduction of about 14 to 25% in fatigue strength due to the action of the corrosive environment. This is similar to the reduction observed by Cahoon and Holte (Ref 130). The fracture surfaces of specimens showing compromised fatigue resistance in saline may not show observable signs of corrosion (Ref 11). A reduction in fatigue strength

due to corrosive action was not always seen in Table 11, however. For recrystallized, as opposed to cold-worked stainless steel, no evidence of CF can be seen in the table. Similarly, when a plasma protein (fibrinogen) was incorporated into the environment, no decline in σ_{fs} was seen. For cold-drawn 316L, the 10^7 cycle endurance limit has been reported to be 530 to 700 MPa (77 to 102 ksi) ($R = -1$) (Ref 131).

Jones et al. (Ref 58) performed fatigue tests at 1 Hz on smooth and notched samples of cold-worked 316L and a transformation-induced plasticity (TRIP) steel in Tyrode's solution and in argon at 37 °C (98.6 °F). They calculated the fatigue life ratio (FLR), that is, the ratio of the number of cycles of life at a given maximum stress in the solution to that in the inert environment. They observed that the reduction in fatigue life was a function of applied potential. Fatigue life ratio values for 316L were in the range of 0.26 to 1.07. The TRIP steels showed even more sensitivity to CF. Gill et al. (Ref 132) tested cold forged 316L at 5 Hz ($R = 0.1$) in 25 °C (77 °F) 0.9% NaCl solution and found the endurance limit to be 424 MPa (61 ksi). No air control values were reported.

Zardiackas et al. (Ref 129) conducted a recent study of the CF behavior of various stainless steel implant alloys. A comparison of their results with the other values in Table 11 reveals some very interesting findings. They fatigue tested three alloys in both water and in Ringer's solution: implant-quality 316L, a nitrogen-strengthened alloy (ASTM F 1314), and Bio-Dur 108 (Thin Film Technology, Inc.), a low-nickel-content stainless steel. First of all, their σ_{fs} value in deionized water for 316L was 480 MPa (70 ksi). This is about $1/3$ higher than the next highest value shown in Table 11 in air. This clearly demonstrated that the more stringent attention that has been paid to alloy cleanliness and metallurgical quality in the past 25 years or so has brought significant benefits in improving the fatigue strength of this implant alloy stainless steel. Their fatigue strength value for 316L in Ringer's solution was 2.7% lower than the value in water. Comparing the other data in Table 11 with this result, it can be inferred that water itself significantly lowers the fatigue strength of 316L, with the chloride content of Ringer's solution providing further deterioration in the σ_{fs} value.

Composition changes to improve the mechanical properties of implant alloy stainless steel also resulted in pronounced enhancement of σ_{fs} . The fatigue strength values at 10^6 cycles were 647 and 608 MPa (94 and 88 ksi) for the F 1314 alloy and for Bio-Dur 108, respectively. For these materials in Ringer's solution, the fatigue strength values were 8.3 and 3.5% less than in water. Additionally, this research was conducted using the ASTM F 1801 (CF testing) experimental protocol, rather than tests in bending or alternating tension-compression, which can significantly affect the fatigue curve.

Windler and Steger (Ref 133) also tested one of the newer stainless alloys in air. They took samples from forged THR femoral components made from a higher nitrogen alloy (ASTM F 1586) and measured the 10^7 cycle fatigue strength in air at 100 Hz using rotating bending at $R = -1$. They found a σ_{fs} value of 587 MPa (85 ksi). Tikhovski et al. (Ref 134) investigated an experimental high-nitrogen (0.75 to 1.0 wt%), low-nickel, Cr-Mn-Mo-N austenitic stainless steel. They reported that its endurance limit in physiological media at 5 Hz was 302 MPa (44 ksi), compared to the following implant-grade alloys:

Alloy	Endurance limit	
	MPa	ksi
Co-29Cr-6Mo	200–280	29–41
CP Ti grade 2	230–280	33–41
316L	250–320	36–46
ISO 5832-9(a)	400–420	58–61
Ti-6Al-4V	400–450	58–65

(a) Nitrogen-containing steel

The endurance limit in air for the Cr-Mn-Mo-N steel was 346 MPa (51 ksi). Eschbach et al. (Ref 135) also provide results from fatigue tests using actual implants fabricated from a low-nickel, high-nitrogen steel. Compared to 316L or titanium implants, they found that the low-nickel steel had less HCF resistance.

Various studies of the CF behavior of 316L have also been conducted using the fracture mechanics approach. Wheeler and James (Ref 81) used square wave loading to approximately simulate the gait cycle and found that fatigue crack growth was enhanced in Ringer's solution compared to air. For the constants

Table 11 Fatigue strength of 316L stainless steel measured in air, deionized water (DI), and in Ringer's solution

Fatigue strength, MPa (ksi)					
Environment					
Air	DI	Ringer's	Change, %	Remarks	Ref
281 (41)	...	241 (35)	−14.2	Solution pH: 6.5	97
246 (36)	...	246 (36)	...	Recrystallized	10
339 (49)	...	292 (42)	−13.9	Cold worked	10
362 (52.5)	...	271 (39)	−25.1	EP	14
362 (52.5)	...	370 (54)	+2.2	EP, Ringer's containing fibrinogen	14
...	480 (70)	467 (68)	−2.7	...	129

EP, electropolished

in the Paris equation, they found that in air $A = 1.442 \times 10^{-24}$ and $m = 4.151$, when da/dN is given in units of in./cycle and ΔK is in $\text{psi}\sqrt{\text{in.}}$. In Ringer's solution, the values were $A = 6.222 \times 10^{-21}$ and $m = 3.382$. Colangelo (Ref 136), on the other hand, tested 316L in air and in 0.9% NaCl using a frequency of 30 Hz and actually found higher crack growth rates in air in the lower ΔK range. Here, m was 3.23 in air and 4.16 in the saline solution. These studies were, of course, not conducted on 316L samples with the current stainless steel composition range.

For 316L tested in 1 M NaCl, anodic polarization enhances crack growth rates, while cathodic polarization exhibits the opposite effect (Ref 137). Taira and Lautenschlager (Ref 138) used potentiostatic techniques on fatigue loaded cold-worked 316L specimens and found that the accelerated corrosion combined with the dynamic mechanical loading disturbed the repassivation process, which led to reduced crack initiation times and fatigue life, compared to control samples tested in air. Nakajima et al. (Ref 139) examined the crack growth rate behavior of two stainless steels, said to be used for biomaterials applications, which have chemical compositions in accordance with Japanese (JIS) standards, which are quite different than those falling within the ASTM specifications. One of these alloys, SUS 304, is presently used as a biomaterial, while the other, SUS 329J4L, is described as a duplex stainless steel under consideration for use within the body. For the first alloy, they found da/dN is faster in Ringer's solution than in air for $\Delta K \geq 25 \text{ MPa}\sqrt{\text{m}}$ (23 $\text{ksi}\sqrt{\text{in.}}$), but the crack growth rate was similar in each case when the range of stress intensity applied was lower than that. For SUS 329J4L, the da/dN versus ΔK curves were similar in both test environments. Further information on CF behavior of 316L in solutions intended to simulate *in vivo* conditions is given by Imam et al. (Ref 59), Piehler et al. (Ref 140), and Higo and Tomita (Ref 141).

Titanium Alloys. Most investigators who have performed fatigue and CF tests with titanium-base implant alloys have observed a clear fatigue limit. For CP Ti, Pohler (Ref 142) found that the endurance limit σ_{el} was 342 and 374 MPa (50 and 54 ksi) for recrystallized and cold-worked material, respectively. For the cold-worked biomaterial tested in Ringer's solution, the value was 322 MPa (47 ksi), 13.9% less.

Regarding Ti-6Al-4V, Higo and Tomita (Ref 141) found σ_{el} was about 400 MPa (58 ksi) whether smooth specimens were tested in air or saline solution, although they do not report the frequency used for the testing. In their fracture-mechanics-based experiments, it was noted that da/dN was slightly higher in 0.9% NaCl compared to in air. Bratina et al. (Ref 36) report that the fatigue strength for the mill-annealed version of the ELI alloy is about 625 MPa (91 ksi) at 10^7 cycles ($R = -1$). Hoepfner and Chandrasekaran (Ref 143) tested Ti-6Al-4V in an experimental configuration that combined fatigue loading and

fretting damage. They noted a marked reduction in fatigue resistance. At a maximum cyclic stress of 524 MPa (76 ksi), the fatigue life was reduced to about only 7×10^4 cycles when there was a fretting component corresponding to a 41.4 MPa (6 ksi) normal stress.

Cook et al. (Ref 144) performed high-speed (10,000 rpm) rotating beam tests on Ti-6Al-4V ELI specimens (prepared in a variety of ways) in air and isotonic saline solution. They found no difference between the results in the two test environments, but observed large differences depending on how the specimens were fabricated. The endurance limits for as-received and ultralow-temperature isotropic (ULTI) carbon-coated samples were 617 and 624 MPa (89 and 91 ksi), respectively. When the biomaterial was notched, σ_{el} fell to 230 MPa (33 ksi). For specimens that were given the sintering heat treatment cycle used for porous coating, the endurance limit was 377 MPa (55 ksi), and for porous-coated specimens themselves, it was only 138 MPa (20 ksi). Particle size is also a factor as to why the endurance limit of the porous-coated titanium alloy can be considerably reduced (Ref 36). Besides the notch and particle size effects, the sintering cycle unavoidably will create a β -transformed microstructure. It has been estimated that the minimum value of σ_{el} needed to avoid failure of a hip prosthesis is 400 MPa (58 ksi) (Ref 145).

Kohn and Ducheyne (Ref 146) performed a study to separate out the effects of interface geometry, microstructure, and surface changes arising from the sintering process. For smooth Ti-6Al-4V they saw that alloying with hydrogen raises the fatigue strength to 643 to 669 MPa (93 to 97 ksi), compared to β -annealed Ti-6Al-4V (497 MPa, or 72 ksi) or preannealed equiaxed Ti-6Al-4V (590 MPa, or 86 ksi). The σ_{fs} value of porous-coated samples, though, was found to be independent of microstructure, and sintered neck junctions were observed to serve as immediate crack initiators so that, in this case, the fatigue behavior is propagation controlled. Kohn et al. (Ref 147) reported fatigue strength values of various heat treatment/microstructure conditions of porous-coated Ti-6Al-4V to span the 177 to 233 MPa (26 to 34 ksi) range. They used acoustic emission and finite-element techniques to determine fatigue mechanisms, to detect incipient damage and monitor its accumulation, and to calculate localized stress patterns. In a related study, Kohn et al. (Ref 148) saw that the sequence of steps involved in the fracture of porous-coated materials was transverse fracture in the porous layer, sphere/sphere and sphere/substrate debonding, initiation of a fatigue crack in the substrate, slow propagation, and finally fast propagation of the crack. For the smooth Ti-6Al-4V alloy, Shetty (Ref 149) prepared nitrogen diffusion hardened (NDH) specimens and tested them in air at 30 Hz ($R = 0.1$). He found that the 10^7 cycle fatigue strength was almost the same as the control alloy (490 MPa, or 71 ksi, for the base alloy compared to 496 MPa, or 72 ksi, for the NDH form).

Besides the weakening effect of a notch, plastic deformation also has a deleterious effect. Brunner and Simpson (Ref 108) provide data indicating that σ_{el} in bending falls by more than 50% for titanium plates that have been plastically deformed, compared to intact, nonbent plates.

Hampel and Piehler (Ref 150) also studied the CF behavior of smooth and porous-coated Ti-6Al-4V. In this case, however, the porous layers were not produced by sintering, but rather by an etching technique or by plasma spraying. They tested the behavior in axial loading at 6 Hz ($R = 0.1$) in 37 °C (98.6 °F) Ringer's solution. The 10^7 cycle endurance limit for the smooth specimens was 414 MPa (60 ksi), and for the etched samples it was 380 MPa (55 ksi). For plasma sprayed material, on the other hand, the samples fractured at about 10^5 cycles at 242 MPa (35 ksi). Wolfarth and Ducheyne (Ref 151) devised a new type of coating geometry (termed the porous-coated nodule) that lowered stress concentrations and raised the fatigue strength up to 305 MPa (44 ksi) for this alloy.

Bratina et al. (Ref 36) found that both mill-annealed and β -transformed alloys show well-defined fatigue striations; although, on fracture surfaces of the latter alloy type, large facets indicative of fast crack propagation sometimes were observed. Also, crack growth rates determined from striation spacing disagreed with macroscopic da/dN measurements, again, particularly in the β -transformed alloy, in part due to tortuosity of the crack path. The striated region only accounted for about 10% of the fatigue life, indicating the importance of the initiation phase on the total lifetime. A similar result was noted for 316L.

Bourassa et al. (Ref 152) examined microknurling of the surface as an alternative for porous coating of titanium alloys, so that the preparation of the textured surface would not have such adverse effects on fatigue strength. Since surface stress concentrations are still present with this type of material, they tried to use heat treatment to achieve a duplex microstructure that would optimize fatigue resistance. This microstructure consisted of equiaxed surface grains (to resist crack initiation) and a bulk lamellar microstructure to retard crack propagation. This attempt was only partially successful.

Nakajima et al. (Ref 139) used a fracture mechanics approach to investigate the CF behavior of CP Ti and Ti-6Al-4V. For the commercially pure material, they found that the da/dN versus ΔK behavior was quite similar in air and Ringer's solution. For the Ti-6Al-4V alloy, however, they saw that, as with SUS 304, when ΔK equals or exceeds $25 \text{ MPa}\sqrt{\text{m}}$ (23 $\text{ksi}\sqrt{\text{in.}}$), crack growth is enhanced in Ringer's solution compared to air, while below this range, the rate of crack growth is comparable in each environment. Feige and Kane (Ref 87) did not see an increase in crack growth rate in saltwater, compared to air, until the ΔK value used approached K_{ISCC} . Comparing the fatigue response of Ti-6Al-4V in air, distilled water, and saltwater,

McEvily (Ref 137) presents data indicating that, at a given ΔK value, the crack growth rate is fastest in saltwater, slowest in air, and intermediate for the distilled water environment. He also provides experimental results which show that, in saltwater in the higher ΔK region, da/dN increases as the loading frequency decreases from 10 down to 1 Hz. In another study presented by McEvily (Ref 137), in a halide environment, increasing the electrode potential led to an increase in the rate of crack propagation.

Zavanelli et al. (Ref 153) studied the CF behavior of CP Ti and Ti-6Al-4V by testing in air, artificial saliva, and a fluoridated synthetic saliva solution. This investigation was motivated by the fact that these alloys are used for the framework of removable partial dentures. They observed that the fatigue life was significantly reduced in the solutions compared to dry air. In a study following a similar experimental protocol, they found that laser repairing of these alloys also adversely affects corrosion fatigue life (Ref 154).

A number of investigators have studied the fatigue behavior of newer compositions of titanium alloys. Bhambri et al. (Ref 155) performed rotating cantilever fatigue tests in air at 30 Hz ($R = -1$) on Ti-15Mo β titanium alloys. They found the 10^7 cycle σ_{fs} values to be in the 450 to 518 MPa (65 to 75 ksi) range, depending on alloy composition and heat treatment. Wang et al. (Ref 156) tested another β titanium alloy, Ti-12Mo-6Zr-2Fe, in air at 167 Hz ($R = -1$) and observed a 10^7 cycle σ_{fs} value of 585 MPa (85 ksi) for smooth specimens and 70% of that value for notched material. This compared favorably to their tests with Ti-6Al-4V under similar conditions (280 MPa, or 41 ksi, smooth and 53% of this when notched). Mishra et al. (Ref 157) tested Ti-13Nb-13Zr (a near- β alloy) in the smooth condition ($K_t = 1$) and at two notched conditions (K_t values of 1.6 and 3.0) using axial loading in air ($R = 0.1$, 60 Hz). In order of increasing notch severity, the 10^7 cycle endurance limit was 425 to 500, 335, and 135 to 215 MPa (62 to 73, 49, and 20 to 31 ksi). The analogous values for annealed Ti-6Al-4V were 500, 320, and 170 MPa (73, 46, and 25 ksi). More recent studies of innovative titanium-base implant materials are covered in the section "New Materials and Processing Techniques for CF and SCC Prevention" in this article.

Roach et al. (Ref 158) have investigated the CF behavior of a series of titanium-base implant alloy materials including α , α/β , and β alloys. They tested notched and unnotched samples in distilled water and Ringer's solution at 1 Hz. They found no difference in fatigue strength values between the two test environments, indicating the presence of chloride in this case did not adversely affect the fatigue resistance. On the other hand, they noted there was a pronounced weakening due to the presence of the notch. The fatigue strength values at 10^6 cycles, as well as the fatigue notch factors, for the various alloys tested are given in Table 12. The F 1295 α/β alloy (Ti-6Al-7Nb) exhibited the most fatigue

resistance in smooth specimens, while the F 2066 β titanium alloy (Ti-15Mo) showed the least. For notched samples, Ti-6Al-4V ELI showed the greatest notch sensitivity, while the F 2066 alloy was least notch sensitive. As is the case with the stainless steel alloys, this study illustrates the improvements that have been made since roughly the 1970s regarding the performance of titanium alloys through changes in alloy composition and processing techniques. In another investigation using a similar experimental design, it was shown that anodizing of CP Ti grade 4 did not affect the fatigue behavior of either smooth or notched specimens (Ref 159).

Morphologically, the appearance of titanium alloy fracture surfaces is more complex than for the stainless steels (Ref 11). Since there are a limited number of operative slip systems in the hcp structure, twinning is also involved in plastic deformation. Depending on the local stress and the crystallographic orientation in the crack plane, regions of widely varying striation density can be found in close proximity, and a variety of additional features, such as terraces, tearing ridges, and dimples, may be present.

Cobalt-Base Alloys. Less work has been done on the cobalt-base implant alloys than for the other systems. Most reports available are of fatigue testing in air. Pohler (Ref 142) reports the endurance limit of a cobalt alloy is 450 MPa (65 ksi) when cold worked and is 240 MPa (35 ksi) when soft. Bratina et al. (Ref 36) report that the fatigue strength of the F 75 alloy at 10^7 cycles is 300 MPa (44 ksi) without a homogenizing solution treatment, which is reduced to 250 MPa (36 ksi) with this heat treatment. Pohler (Ref 11) reports that the fatigue initiation process in the F 563 alloy is similar to that for stainless steel, but that the fracture surfaces have a greater striation density.

Georgette and Davidson (Ref 160) performed studies of the influence of a porous coating on the fatigue resistance of cobalt-base alloys that were similar to those for the titanium-base system described in the prior section. They found that the fatigue strength of as-sintered Co-Cr-Mo material was 34% less than as-cast. The same material when subjected to hot isostatic pressing, however, had a σ_{fs} value just slightly below that of the as-cast condition. Porous coating was found to create crack initiation sites, but the σ_{fs} value was no lower than for the as-sintered condition. The fatigue strength of the porous-coated material improved when the material was hot isostatically pressed.

Berlin et al. (Ref 161) investigated the fatigue behavior of both cast and wrought Co-Cr-Mo alloys in air and found abrasive surface blasting had little influence on the fatigue strength. Laser marking, on the other hand, significantly reduced it for both the cast and wrought versions of the F 75 material. They also found postcasting processes had significant effects on fatigue resistance. The σ_{fs} values at 10^7 cycles for as-cast, hot isostatically pressed (HIP) and solution treated (ST), sintered, and sintered plus HIP plus ST for F 75 were 340 to 480, 380 to 450, 210 to 275, and

345 to 380 MPa (49 to 70, 55 to 65, 30 to 40, and 50 to 55 ksi), respectively. For the wrought version of this material (F 1537), the properties can also be improved by thermomechanical processing. The σ_{fs} values for this alloy in the mill-annealed, warm-worked, and forged conditions are 483, 690, and 759 to 828 MPa (70, 100, and 110 to 120 ksi), respectively. Mishra et al. (Ref 162) tested samples made from either a high-carbon version of F 1537 (CCM Plus) or the F 75 alloy. The samples were porous coated or else subjected only to the sintering cycle. They found σ_{fs} values at 10^7 cycles for porous-coated material were 241 and 207 MPa (35 and 30 ksi) for CCM Plus and F 75, respectively. In the mock-sintered condition, the values were 345 MPa (50 ksi) for F 75 and 448 to 690 MPa (65 to 100 ksi) for CCM Plus (Carpenter Technology Corporation). This same research group also reported on the fatigue properties of an oxide-dispersion-strengthened version of the F 799 alloy known as gas-atomized dispersion-strengthened (GADS) (Ref 163). Using rotating bending techniques, the fatigue strength at 10^7 cycles was 690 to 895 MPa (100 to 130 ksi) as-forged and 620 MPa (90 ksi) for material subjected to the sintering heat treat cycle. In four-point bending, the σ_{fs} values were 670 MPa (97 ksi) for the sintered GADS material and 345 MPa (50 ksi) for the porous-coated alloy. For the F 90 alloy, the fatigue strength is about 207 MPa (30 ksi) in the annealed or solution treated condition, while for an alloy solution treated and cold worked 20%, the value rises to about 428 MPa (62 ksi) (Ref 18). For MP35N the fatigue strength is 186 MPa (27 ksi) in the annealed condition and 745 MPa (108 ksi) when it has been aged and cold worked 40% (Ref 18).

There have been only a few CF studies of a cobalt-base biomaterial. Sury and Semlitsch (Ref 164) found that a wrought Co-Ni-Mo-Ti alloy was superior in terms of CF resistance compared to cast Co-Cr-Mo, and the SCC resistance of the materials was equal. Bolton et al. (Ref 93) used a fracture mechanics approach and found a cast Co-Cr-Mo alloy was vulnerable to CF. The crack propagation rate was significantly higher in Ringer's solution compared to that in air. For fine-grained material, they found the constants in the Paris equation were $m = 2.2$ and $A = 1.35 \times 10^{-11}$ for testing in air (when da/dN was in units of m/cycle and ΔK in units of $\text{MPa}\sqrt{\text{m}}$). For Ringer's solution, they were $m = 2.33$ and $A = 3.5 \times 10^{-11}$. For fine-grained material tested in air, m was 4.3 and

Table 12 Fatigue strength of smooth and notched specimens of various titanium alloys

Alloy	UNS designation	Fatigue strength		Fatigue notch factor, K_f
		MPa	ksi	
CP Ti grade 4	R50700	550	80	2.75
Ti-6Al-4V ELI	R56407	700	102	4.67
Ti-15Mo	R58150	500	72.5	2.50
Ti-6Al-7Nb	R56700	750	109	...

A was 2.10×10^{-14} . For this material in Ringer's solution, the constants were $m = 2.4$ and $A = 1.14 \times 10^{-11}$. Lassila and Vallittu (Ref 165) performed LCF testing on a cast Co-Cr alloy used to make clasps for removable partial dentures. They found testing in water or in artificial saliva (Fusayama's solution) reduced the fatigue strength of this material compared to testing in a dry environment.

Comparative Studies of the Various Implant Alloys. Several researchers have conducted studies that allow the CF behavior of the basic orthopedic alloy systems to be directly compared. Nakajima et al. (Ref 139) used a fracture mechanics approach and found for four implant alloys tested, the crack propagation velocities ranked as:

CP Ti > Ti-6Al-4V > SUS 304 > SUS 329J4L

Imam et al. (Ref 59) conducted torsional CF studies in Hanks' solution. They found that when tests on smooth specimens of three implant alloys were carried out with a constant amplitude cyclic strain, the fatigue life of the metals had the ranking:

Ti-6Al-4V > 316L > Co-Cr-Mo

The comparison between Ti-6Al-4V and 316L exhibited previously is consistent with the findings of Piehler et al. (Ref 140), who found the CF performance of the titanium alloy was markedly better than that of 316L, even when significant fretting and wear was involved. Cornet et al. (Ref 166) also found CF performance of titanium alloys to be superior to that of cobalt-base and stainless steel alloy systems.

When Imam et al. (Ref 59) conducted tests in which the stress amplitude was fixed, instead of the strain, the same ranking as given previously was observed at a high level of stress. At a lower applied stress, however, the fatigue life ranking was:

316L > Co-Cr-Mo > Ti-6Al-4V

Rotating bending fatigue tests in air, conducted at 100 Hz by Semlitsch et al. (Ref 145), showed fatigue strength ranges for Co-Cr-Mo, Ti-6Al-4V, and Co-Cr-Mo-Ni alloys were 500 to 800, 600 to 660, and 400 to 780 MPa (73 to 116, 87 to 96, and 58 to 113 ksi), respectively. Whitaker (Ref 167) compared the CF behavior of 316 stainless steel and two titanium alloys, indicated as titanium alloys 130 and 318. He investigated the influence on CF of drilling of holes in bone plates for fitting and of the lowered pH that can be found in patients suffering from shock or may be found in the crevice between the plate and the underlying material. The CF resistance of the stainless steel was poor in the low-pH environment, but was unaffected by drilling. The titanium alloys were less affected by the acidic pH, but were more sensitive to drilling.

Pilliar (Ref 112) has summarized various improvements in materials and implant design that produced more fatigue-resistant implants. He points out that the introduction of the mill-annealed Ti-6Al-4V alloy and forged high-

strength cobalt-base alloys into the orthopedic inventory was largely motivated by concerns over fatigue failure, primarily of THR femoral component stems. In addition, design changes were introduced, for example, heavier stem designs with a greater section modulus. This, however, runs the risk of an increase in problems related to stress shielding. For porous-coated devices, improved designs incorporated the knowledge that such layers should be put in the areas of the implant where the device would be highly stressed in tension. Pilliar (Ref 112) also points out that other high-fatigue-strength alloys were introduced for implant use in the 1980s—duplex stainless steels and powder-metallurgy Co-Cr-Mo alloy components made by hot isostatic pressing. The latter materials have a fine grain size (~5 to 10 μm), compared to 100 μm or greater for conventionally cast parts. The carbide distribution also enhances the fatigue strength of these powder-metallurgy parts.

Dental Amalgam. Though many mechanical properties of dental amalgam have been extensively studied, for example, tensile strength, bending strength, compressive strength, creep behavior, and so forth, the fatigue behavior of dental amalgam has received much less attention. Wilkinson and Haack (Ref 168) measured the fatigue limit of an amalgam to be about 97 MPa (14 ksi). Mateer and Reitz (Ref 164) metallographically examined amalgam restorations that had deteriorated during clinical service and found evidence of fatigue cracking, particularly in the vicinity of the margin. Sutow and Jones (Ref 170) also performed fatigue tests and found that the stresses that would fracture amalgam, due to dynamic fatigue loading, were substantially below the static fracture strength. They pointed out that clinical failures might be caused by CF. Hero et al. (Ref 171) performed a controlled study of the behavior of various amalgams under both static and dynamic loading conditions. They observed SCC associated with creep in the static testing. For the fatigue loading, the influence of creep was also noted, but the strains were much less than for the static loading case. A significant SEIR effect was noted for the fatigue loading case. Lian and Meletis (Ref 172) investigated the combined influence of sliding wear and corrosion on the performance of dental amalgam specimens. They observed that this combined action can induce embrittlement and cracking and suggested this may be a major contribution to marginal failures of amalgam restorations.

Findings from *in vivo* Testing and Retrieval Studies Related to Fatigue and Corrosion Fatigue

Retrieval studies form an important part of the knowledge base related to implant failure *in vivo*. ASTM standard F 561 describes guidelines for analyzing implant failures. Over the years, there have been quite a number of reports of metallic

surgical implant alloys that have failed by fatigue or CF. One of the first systematic investigations that attempted to examine the underlying metallurgical causes for failure of such devices was the work of Cahoon and Paxton (Ref 173). They investigated a number of fractured 316L and cast Vitallium (the ASTM F 75 composition) implants, most of which they determined had failed by fatigue or CF, with one 316L implant possibly being a case of SCC. They observed a number of metallurgical and engineering defects (excessive inclusion content, casting porosity, large grain size, stress raisers due to poor design, severe plastic deformation and martensite formation, sensitization, and possibly a molybdenum content that was too small) that were the cause(s) of these failures. Colangelo (Ref 136) investigated a number of 316L implants that had fractured. The failure mechanism was fatigue. Corrosion was involved in the initiation of cracking, but Colangelo was uncertain whether it played any role in crack propagation. Similar conclusions were reached by Colangelo and Greene (Ref 174). In implants that had not yet been implanted, they observed some examples where fine hairline cracks were present, and other cases where there was significant surface porosity.

Hughes and Jordan (Ref 175) examined several stainless steel and titanium implants that failed in service. Fatigue, CF, and SCC failure mechanisms were observed for stainless steel. The titanium implant failed by overload fracture originating at a spark-etched trademark, a stress raiser the investigators felt would eventually have led to a fatigue failure after a more extended period of service. Weinstein et al. (Ref 176) reported on fatigue failures in two stainless steel intertrochanteric implants. One occurred in an implant with a recrystallized microstructure with many annealing twins and exhibited tire tracks upon fractographic analysis. Three other implants (two Vitallium and one stainless steel) had not failed, but were cracked. In another early study of biomaterials made of cobalt-base alloys that failed in service, Bates and Scott (Ref 177) showed evidence of fatigue failure in partial dentures. Lisagor (Ref 178) reports on three fracture fixation devices (nails and plates) that failed by fatigue or CF where pitting, crevice corrosion, or fretting were initiating factors. Two were made of 316 stainless steel, while the third was Vitallium. Ducheyne et al. (Ref 179) reported on a retrieved 316 stainless steel implant that failed by CF.

Dumbleton and Miller (Ref 6) describe a fatigue fracture of an intramedullary nail. The surface exhibited pitting near the fracture origin, but it could not be determined whether or not the corrosion played a role in the failure. Corrosion fatigue was implicated in another case study they reported involving a Thornton nail-and-plate device in which the two components were made from dissimilar cobalt-base alloys (ASTM F 75 and F 90). Hochman et al. (Ref 180) discuss the results of an examination of more than 500 retrieved implants that had fractured or failed in

some other fashion. In the vast majority of cases (nearly 98%), the major cause of failure of the implant was listed as fatigue, in some cases accelerated by the *in vivo* environment. Wright et al. (Ref 181) report on another extensive retrieval study in which they found 65 fractured total hip replacement femoral components (29 316L implants and 36 cobalt-base implants, 35 ASTM F 75 and one F 90). In some cases, metallurgical defects, notably casting porosity, and stress raisers caused by surface damage resulting from surgical implantation or else fretting due to rubbing against a trochanteric wire were implicated in the failure. Fatigue fractures of total knee replacements also were observed, depending on the implant design.

Pohler (Ref 11) describes fatigue fracture of Co-Cr-Mo Moore pins. Brittle precipitates, alloy segregation, porosity, and inclusions were implicated in the failure. The pins did not exhibit visible corrosion, and the fracture surface was mixed mode with domains with dimples and fatigue striations. In another case, cerclage wire cracked in an intercrystalline manner. The wire was made of 304 stainless steel in the sensitized condition and was in contact with 316L components. Fatigue failure was also noted in bone screws with a high inclusion content. She also describes other examples where implants of high quality that met applicable standards suffered fatigue for mechanical and biomechanical reasons, for example, instability and nonunion leading to pseudoarthrosis. Baswell et al. (Ref 182) examined 10 retrieved 316L wires used for trochanter reattachment or in L-rod instrumentation. They observed 16 fractures, 94% of which were caused by fatigue. Similar to the findings of Coquillet et al. (Ref 109) discussed previously, they noted that wire deformation influenced fatigue life. Pitting of the wires was also thought to be a possible influence on crack initiation. Novak et al. (Ref 183) also observed CF in retrieved orthopedic wires.

Zardiackas et al. (Ref 184) performed a retrieval study involving 275 long bone plates and implants used to treat hip and knee fractures. Of these, 17 stainless steel implants had fractured in service. The mechanism of failure was fatigue, in some cases exacerbated by fretting corrosion. A metallurgical analysis was performed on the broken implants, and all were seen to be within the ASTM specifications in terms of Vickers hardness, oxide inclusion content, grain size, and δ -ferrite content. Pohler (Ref 185) indicated, in the vast majority of cases, failure of long-bone implants were caused by wrong indications for their use, improper use of the implant, or incorrect application of the implant (leaving the fracture with inadequate reduction and insufficiently rigid fixation). The findings of Zardiackas et al. were consistent with this. The reasons they identified for the failures were bone loss, heavy comminution, nonunion, extensive involvement of soft tissue, osteoporotic bone, and premature weight bearing.

Bratina et al. (Ref 36) performed retrieval analyses on implants fabricated from all the

common metallic systems. In Co-Cr-Mo they saw that fatigue crack growth occurred along slip planes for both stage I and stage II. Fractographically, more or less featureless facets were observed, but at higher magnification there was a complex topography with crystallographically controlled propagation and striations in some locations. Obstacles in the crack path were said to provide barriers that could stop propagation for perhaps many thousands of cycles, after which the crack would rapidly advance for a considerable distance following a tortuous path. They noted casting porosity and surface damage due to inappropriate fabrication and handling could provide crack initiation sites. They also noted, though, that the precision investment casting methods now in use made the first type of defect unexpected in medical devices. Thus, the failures noted with the Bjork-Shiley heart valve, described later, were surprising. Absent such defects, crack initiation was noted to arise from various microstructural features: coarse grain size, grain boundaries, coarse precipitated carbides, and bead-substrate interfaces (in components prepared with powder-metallurgy techniques).

In contrast to the cobalt-base system, Bratina et al. (Ref 36) observed that fatigue fractures in the CP Ti, Ti-6Al-4V ELI, and 316L alloys do tend to show classical fatigue patterns with clear crack origins, beach marks, and distinct patterns of striations. For CP Ti Brånemark single-tooth replacements, striation morphology of fracture surfaces of fixture portions that had failed were consistent with CF and had a spacing on the order of 0.5 μm . The more common fracture site in these devices is in the abutment screw or the gold coping screw (Ref 186). Bratina et al. point out that the corrosive action of body fluids can serve to obliterate fatigue striations and that counts on retrieved specimens may represent as low as 50% of the actual number of loading cycles.

Besides propagating fatigue cracks, microcracks, short cracks, and arrested nonpropagating cracks were observed in the Ti-6Al-4V alloy by Bratina et al. They point out that identification of the initiation stage may be difficult, both because it may be confined to a very localized region only a few grains thick, and since it is the most damaged portion. Even so, initiation is the critical factor for surgical implant alloys, since so much of the total fatigue life is consumed in that stage.

Bratina et al. (Ref 36) also examined failed Harrington rods made from 316L stainless steel that, in some cases, had fracture surfaces so damaged that fractographic analysis showed only abrasion traces. In other cases, the true fracture surface could be observed, and the fatigue portion was about 50% of the surface, with striation spacings being in the 0.15 to 0.5 μm range and increasing with crack length. The ΔK is not known, but based on results of laboratory studies, a 0.1 μm spacing corresponds to 15 $\text{MPa}\sqrt{\text{m}}$ (14 $\text{ksi}\sqrt{\text{in.}}$), while 1 μm represents 35 $\text{MPa}\sqrt{\text{m}}$ (32 $\text{ksi}\sqrt{\text{in.}}$). The stage II phase was

estimated to represent less than 10% of fatigue life. The Harrington rod device is intended to promote spinal fusion, which should gradually relieve the load. If this does not occur, the device is vulnerable to fatigue fracture, usually originating at the junction between the first ratchet and the shaft. This sort of failure is design related, but modification of the implant design to avoid this would be difficult. Both the notch effect and the influence of stress corrosion were thought to be implicated in the failure of these devices. These investigators feel stress corrosion plays a major role in the fatigue behavior of surgical implant alloys.

In a 316L Charnley THR femoral component Bratina et al. examined, macroscopically it appeared that most of the fractured area represented sudden ductile overload fracture; but, detailed scanning electron microscopy (SEM) and transmission electron microscopy (TEM) work actually showed the striation pattern was present over 90% of the surface. This was interpreted as being due to a low-load situation in the implant, with the bone bearing a significant amount of the load.

Snyder and Snyder (Ref 187) report on two retrieved 316L bone screws that failed by fatigue initiated at sites of pitting corrosion. They attributed the failure to the use of work-hardened material, which was said to be more notch sensitive than the annealed alloy. According to these investigators, cold working reduces the fatigue strength from about 760 MPa (110 ksi) for unnotched material, down to 170 MPa (25 ksi) with a notch present. In contrast, annealed material has a fatigue strength of 230 MPa (33 ksi) and is notch insensitive. They recommend that type 317L stainless steel be used in lieu of 316L. Unfortunately, the higher molybdenum content in 317L can promote the formation of secondary phases such as δ -ferrite and σ phases that are not acceptable in implant-quality stainless steel.

Gilbert et al. (Ref 188) reported on two cases of CF failure of modular cobalt-alloy head/cobalt-alloy stem modular THRs. The cracks were located within a millimeter of the taper junction, and the fractures were intergranular. Three factors were seen to be responsible for the failures: grain-boundary porosity, intergranular corrosion, and cyclic loading.

In another investigation, Zardiackas and his coworkers reported further on findings from their retrieval study work (Ref 9). This work is particularly useful, since it very clearly describes appropriate protocols and aspects to consider for researchers who perform retrieval studies, for example, for surface cleaning; implant sectioning; orientation effects; compositional analysis using x-ray fluorescence (XRF), energy-dispersive x-ray analysis (EDX), and wavelength-dispersive spectroscopy (WDS); hardness measurements; grain size and structure determination; inclusion content measurement; intergranular corrosion susceptibility; radiograph interpretation; visual and SEM analysis (and identification of wear, plus mechanisms of

corrosion and fracture); foreign phase identification; and fractographic interpretation. This investigation also points out various pitfalls that may arise during such efforts. Using metallurgical analyses, radiographs, and patient record data (all of which can provide information essential for pinpointing causes of failure), they examined a variety of implants that had fractured in service—a 316L dynamic compression plate, 316L and CP Ti bone screws, an intramedullary nail, a Ti-6Al-4V tibial tray, and a Co-Cr total hip prosthesis stem. None of the devices examined were found to be severely faulty in the metallurgical or engineering sense (i.e., defects in materials, fabrication techniques, or design). The failure mechanism was generally fatigue that arose from nonunion, bone cement deterioration, bone resorption, and patient factors, such as weight. In one case, overload fracture consequent to device removal was observed.

In a study reminiscent of the work of Hughes and Jordan (Ref 175), Naidu et al. (Ref 189) report a case where a retrieved flexible intramedullary nail failed by CF that originated at a mechanically stamped label. They recommend that ASTM standard F 86 (surface preparation and marking of implants) be modified to exclude this type of labeling for cyclically loaded implants.

Magnissalis et al. (Ref 190) observed fatigue fracture in the stem of porous-coated modular THR implants made with Co-Cr-Mo heads and Ti-6Al-V ELI femoral components. The fracture plane went through the proximal portion of the stem where the porous-coated layer was located. It should be noted, this is not the most highly loaded portion of the implant, and these authors indicate their findings verify the concern regarding compromised fatigue strength of porous-coated layers, which was discussed previously.

Pohler (Ref 11) indicates that, over the years, the number of implants failing due to metallurgical causes has diminished as processing techniques have improved, and now most failures occur for mechanical or biomechanical reasons. The review of the failure analyses of retrieved implants given previously underscores this conclusion.

To the authors' knowledge there has been only one research group that has performed CF measurements *in vivo* in an animal model. Morita et al. (Ref 191) built a fixture capable of fatigue testing in the tibia of a living rabbit. They tested type 316 stainless steel and a cobalt-bearing stainless steel (COP), which were both said to be widely used as orthopedic implant materials. For 316, they found 5×10^6 loading cycle σ_{fs} values of 830, 815, 815, and 680 MPa (120, 118, 118, and 99 ksi) for air, saline solution, horse serum, and *in vivo* in the rabbit, respectively. For COP, the *in vivo* value was 680 MPa (99 ksi), compared to 800 MPa (116 ksi) in air. They concluded that the reduction in fatigue strength was due to the low dissolved oxygen content of body fluids. They confirmed this hypothesis in a subsequent study (Ref 192).

Fundamentals of Stress-Corrosion Cracking

For CF, the influence of the environment is generally to diminish fatigue life, although there will be a difference in degree between differing environments in this regard. For SCC, on the other hand, there is a pronounced degree of environmental specificity. A given material will be susceptible to SCC in only a few environments (if any) and will be immune to SCC in the vast majority. The species responsible for SCC need not be present in high concentrations, however (Ref 193). A static tensile stress (applied and/or residual) is necessary for SCC to occur in susceptible material/environment combinations. Often the chemical environment is apparently mild comparatively, and the stress level can be well below σ_y (Ref 105). This accounts for the interest in implant alloy SCC, since such conditions characterize the service environments of surgical implants. It has been stated (Ref 194) that SCC and hydrogen stress cracking represent the two most subtle causes of premature fracture in which corrosion is implicated, because of the lack of warning before failure occurs.

Description of Phenomena

Stress-corrosion cracking involves the conjoint, synergistic interaction of mechanical stress and environmental attack, which ultimately leads to failure by fracture. Understanding of the process requires background in mechanics, metallurgy, chemical thermodynamics, corrosion, and electrochemistry and has been hampered largely because the small scale over which the critical reactions at the crack tip occur precludes direct observation of the processes involved (Ref 137). Nonetheless, SCC has been intensively studied for decades, and many details surrounding the process have been clarified. Because of the many complexities associated with its occurrence, SCC has been called the most intriguing form of corrosion failure (Ref 195).

Types and Stages of SCC. Like CF, SCC is invariably brittle in a macroscopic sense. Stress-corrosion cracks often have a characteristic branching appearance, as shown in Fig. 17. The branching may occur on a macroscopic or microscopic level (see Fig. 17a and b, respectively), depending on the level of stress intensity (Ref 196). On a microscopic scale the fracture may occur in an intergranular (Fig. 18) or transgranular (Fig. 19) fashion.

Differentiating between CF and SCC processes based solely on fractographic evidence is not always a clear-cut procedure, since SCC of 316L, for example, can exhibit striations (Ref 83, 178), normally a signature of stage II CF. However, to the experienced fractographer differentiation between these signatures can often be made. On the other hand, CF processes can be without striations (Ref 197) and may exhibit

secondary cracking in stage II (Ref 9). In a section transverse to the fatigue crack plane, such secondary cracking might be confused with the branching pattern characteristic of SCC. Meyn and Brooks (Ref 197) describe ways to differentiate SCC from striationless fatigue based on fractographic features, known as flutes, that may be characteristic only of SCC. However, recent research on CP Ti, titanium alloys, and even high-nitrogen stainless steels subjected to CF (Ref 132) demonstrates these

Fig. 17 Characteristic branching appearance of stress-corrosion cracks. (a) Unetched macrograph (original magnification: 10 \times) exhibiting stress-corrosion cracking branching in type 316 stainless steel. (b) Etched transverse section (original magnification: 20 \times) of crack tip in type 316 stainless steel specimen that failed by stress-corrosion cracking

alloy systems may show fluting and terraces as a function of localized grain orientation, crystal structure, degree of cold work, and stress-intensity factor. Therefore, fluting is not specific to SCC.

As with CF, it is customary to consider SCC as occurring in multiple phases. Both electrochemical and mechanical factors act as driving forces for the process. During the initiation phase (incubation and nucleation of the crack), localized breakdown of the passive oxide film occurs, and corrosion pits or fissures form. These act as localized stress concentrations from which a crack can nucleate. As the crack propagates in the next phase, mechanical factors become more important (Ref 194). Finally in the last phase, the load-bearing cross section has diminished suffi-

Fig. 18 Stress-corrosion cracking by intergranular decohesion of cold-worked 316 stainless steel at high stress intensity in boiling magnesium chloride

ciently so that overload fracture occurs. An overview of the process is shown in Fig. 20 for a material in which there is no preexisting mechanical flaw or crack. The velocity of crack propagation da/dt is dependent on the stress intensity, and three stages have been identified, as shown in Fig. 21. For a test in which K increases as time goes on (a constant stress test, for example), the crack will not propagate until a threshold value K_{ISCC} is reached. In practice, this is defined (somewhat arbitrarily) as the K value where the velocity is below a certain minimum rate, 10^{-10} m/s, for example. Processes thought to be related to this threshold differ depending on the mechanism of SCC (see the discussion below) and include the critical resolved shear stress for slip (in the slip-dissolution model, also known as the film rupture model), a critical crack opening value that allows mass transport in the crack, or the fracture strain for passive film rupture (Ref 199). In some alloy systems, such as Ti-6Al-4V heat treated to be highly SCC resistant in seawater, ripple loads (small cyclic loads superimposed on a much larger sustained load) can substantially lower K_{ISCC} and the time to failure (Ref 200). Though initiation can be a large fraction of the service lifetime, the mechanisms affecting crack growth are much better understood than are those that influence the crack initiation process. Very little is known about the conditions that control nucleation of SCC cracks (Ref 201), although some local plastic deformation often serves as a precursor for SCC (Ref 105).

Just above K_{ISCC} , the velocity in stage I increases sharply with K in a logarithmic fashion (often reported as proportional to K^4) until a steady-state plateau velocity V_p is reached, which generally is orders of magnitude above

the threshold velocity. The plateau velocity for subcritical crack propagation is thought to result from control of cracking kinetics by a rate-determining step (rds) in a sequence of chemical reactions and processes required for cracking. Depending on the specific mechanism involved (see the next section), the rds might involve, for example, mass transport to the crack tip, reactions in the solution in the vicinity of the crack tip, surface adsorption on or near the tip, surface diffusion, surface reactions, absorption into the bulk material, bulk diffusion to the plastic zone in front of the crack, chemical reactions occurring in the bulk material, or the rate of rupture of atomic bonds (Ref 199). Specific factors that might be involved include film rupture and repassivation rates, the corrosion rate, and environmental factors such as pH and crack tip potential. As stress increases further, the velocity is independent of K and stays at V_p . Finally as the final overload phase is approached, da/dt sharply increases again until fracture occurs.

Mechanisms of SCC. Though cases of SCC were first identified nearly a century ago (Ref 202), a full mechanistic understanding of the process still remains elusive. Environmentally induced cracking processes that occur under static load (SCC, hydrogen damage, liquid metal embrittlement, and solid metal induced embrittlement) share certain similarities (such as being exacerbated by increased stress), but do not share a common causative mechanism (Ref 203). Even within one form of such cracking, SCC in this case, a variety of proposed mechanisms exist. Though at one time it was thought that one unifying mechanism might be found to explain all such phenomena, it is now more commonly thought that no one single mechanism fits

Fig. 20 Overview of the stress-corrosion cracking process. Source: Ref 198

all susceptible materials and circumstances (Ref 202).

In overview, the proposed mechanisms involve either anodic dissolution processes or hydrogen-related cathodic processes (Ref 199, 202). To be accepted as an explanation for a specific material/metallurgical condition/environment combination, a proposed mechanism should be able to explain how cracks are nucleated, the rate of their propagation, and be consistent with the fractographic evidence (Ref 199). Stress-corrosion cracking mechanisms also differ in the effects deemed responsible for the breaking of the atomic bonds at the crack tip. Some are based on electrochemical dissolution, for example, the active path (sometimes termed stress-accelerated dissolution) or slip-dissolution models, which involve removal of material from the crack tip, while others emphasize the importance of ductile or brittle mechanical fracture and separation of material at the crack tip. Models in the latter category consider that the fracture process is aided by interactions with the environment, such as adsorption of environmental species, surface reactions, reactions in the material ahead of the crack tip, and influences on surface films (Ref 199).

For SCC processes that are anodically driven, a thermodynamic requirement is that the chemical conditions in the crack must be such that the passive film is stable, while oxidation of the metal and its dissolution into the electrolyte is possible (Ref 199). In the anodic dissolution models, the walls of the crack remain passive (otherwise the crack tip would blunt, and loss of metal, due to corrosion, would occur much more homogeneously), and the ratio of the distance between the walls and the length of the crack is about 0.001 (Ref 199). The potential difference between a crack tip and the passive film can be substantial, ~ 0.5 V (Ref 204). The greater activity of the metal at the tip relative to that on the walls is a consequence of the greater dynamic strain at the tip. This dynamic strain represents a localized creep process (Ref 205). Though cor-

rosion is a controlling process, it should not be assumed that the crack grows in a manner that can be calculated from the amount of metal that would be lost due to the total amount of charge that is transferred at the crack tip. This lower limit of velocity can be found from Faraday's law to be:

$$(da/dt)_{\min} = i_{\text{ct}}(AW)/zF\rho \quad (\text{Eq 24})$$

where i_{ct} is the anodic corrosion current density for bare metal at the crack tip, AW is the atomic weight, z is the valence of the metal, F is the Faraday constant, and ρ is the density of the metal (Ref 201).

The crack may grow at a rate well above this limit, up to 100 times faster when mechanical fracture processes that cause separation of material at the crack tip are important (Ref 199). Also, discontinuous acoustic emission and the presence of crack arrest marks on crack wall surfaces show that SCC crack growth can, in some cases, occur in a discontinuous fashion as the crack tip is repassivated, and then the passive film is again ruptured. On the other hand, if a film reforms over the crack tip for some period of time, or the crack walls are not passive, then the rate of crack tip advance would be lower than the limit predicted by Eq 24. From the previous discussion, it can be surmised that the ranges of potential where a material would be most susceptible to SCC would be those shown in Fig. 2 where there are transitions between active and passive behavior, and this has been verified by experiment, particularly for transgranular cracking.

One of the most prominent electrochemical dissolution models is termed the slip-dissolution model. According to this theory, under the influence of tensile stress, an emergent slip step will rupture the surface creating a region of unfiled, exposed bare metal surface that will be corrosively attacked rapidly, eventually initiating a crack (Ref 204). In planar slip there will be a large normal stress present at the head of a dislocation pileup (Ref 206), which promotes fracture of the passive film. Preferential planar slip also constrains the ability of the material at the crack tip to plastically deform and restricts blunting of the tip (Ref 206). In high-chloride environments, preferential dissolution along the plane of high dislocation density, created by the planar slip, occurs (Ref 207). Various ideas have been advanced as to what factors control the crack advance rate. These include anodic dissolution only; for mechanical fracture models that often apply to transgranular SCC these include: corrosion tunneling in the propagation direction and mechanical fracture of the remaining ligaments of material (known as the corrosion tunnel model), brittle fracture of the tarnish film or corrosion products that form along the path of localized corrosion, chemisorption-enhanced plasticity, film-induced cleavage, adsorption-induced brittle fracture (also known as the stress-sorption model), and HE (Ref 199).

Factors Influencing Susceptibility to SCC

The features that affect SCC processes are particularly complex and include environmental, electrochemical, mechanical, and metallurgical variables. The main influences are described in this section. It should be recognized that, while almost all SCC data have been obtained in mode I tension or bending, complex engineering components, such as implants, may have torsional and shear loads as well. Mixed-mode loading could well have an influence on SCC (Ref 199).

The previous discussion, for the most part, tends to imply that SCC is a deterministic process, but recently Andresen et al. (Ref 208) have provided an excellent interpretation/critique of this type of thinking. They point out that the concept of a completely defined threshold in parameters such as stress intensity, electrode potential, alloy/condition, temperature, and so forth, above which a material is immune and below which it is susceptible to SCC, can be a misleading one. They indicate that when conditions once thought to convey immunity are probed in well-controlled laboratory tests or in light of a mechanistic understanding of the SCC process, the immunity status often fails to stand up, and finite crack growth rates (though often low) can be produced in such controlled tests. Similarly in industrial plants, SCC of components under conditions once thought to be immune has been observed after longer exposure times. Thus, rather than a "go/no-go" defining threshold for a given parameter, according to this view, there is a continuity of response, and SCC should be considered to be an innately probabilistic process. For example, Jones and Ricker (Ref 199) provide data that indicate that SCC crack propagation velocity for 304 stainless steel declines from 10^{-8} mm/s at 260 °C (500 °F) down to about 2×10^{-12} mm/s at -18 °C (0 °F), but no temperature threshold exists. Though Andresen et al. were discussing the specific case of SCC in hot water, their point should be well taken in terms of its applicability to other environments as well, including *in vivo* conditions.

Influence of the Environment. The main environmental factors affecting the SCC process are the types and concentrations of ions in solution, the partial pressures of dissolved gases, pH, solution viscosity and mixing or stirring, temperature, and the electrode potential that is consequently established (Ref 194, 199). For implant alloys, most attention has focused on the presence of the chloride ion, since the ability of this ion to disrupt passive films is well established and because two of the alloy systems most important for metallic implants, stainless steels and titanium-base alloys, can be vulnerable to SCC in chloride environments under some conditions. However, other factors related to the *in vivo* environment, active physiological bioelectric effects and the presence of proteins in the environment or adsorbed into the biomaterial

Fig. 21 Stress-corrosion crack propagation velocity as a function of K . Source: Ref 98

surface, might also possibly play a role (Ref 5, 209).

In situations where SCC vulnerability exists, the environment will establish a situation of borderline passivity, where most portions of the surface are adequately covered by a passive film so as to be corrosion resistant, but passivity in local areas can be breached, forming focal points for corrosion and cracking. Pourbaix diagrams can be valuable tools for visualizing how environmental factors affect the stability and dissolution regions, as well as the ramification of their influence on the electrode potential of the alloy (Ref 199). However, their application to SCC can be limited by the fact that solution chemistry can be very different at the crack tip compared to the bulk solution. For example, in nearly neutral saltwater for steels, the crack tip pH is about 3.5 and for titanium alloys about 1.5. In addition, for each of these alloy systems, the electrode potential at the tip of a growing SCC crack is below that which allows hydrogen evolution from water to occur (Ref 137). Stress-corrosion cracks can nucleate at places where crevice corrosion is occurring, even when the stresses are less than those present outside of the crevice (Ref 205), presumably because of the difference in chemistry within the crevice compared to the bulk solution.

The factors influencing SCC can be subtle, as pointed out previously, and small changes in the bulk environment can have a dramatic impact on SCC, while much larger changes may have little influence (Ref 199), depending on their influence on crack tip chemistry.

Influence of Composition. At one point it was thought that only alloys were vulnerable to SCC, but it has gradually become apparent that pure metals can experience SCC as well. Small differences in alloy composition (whether intentional, due to accidental addition of impurities, or the result of spatial inhomogeneities in chemical composition) can dramatically affect SCC resistance by substantially influencing passive films, metallurgical conditions, and electrochemical state (Ref 199, 202). Localized microchemistry, such as that due to depletion of elements that form passive films or enrichment of elements that foster active corrosion, can be particularly important. The following three sections consider the various generic alloy systems used to fabricate surgical implants and dental materials in terms of their general resistance to SCC. This provides a general indication of how alloys of a similar character behave (in terms of parameters such as temperature, chloride content, and so forth). The actual experience with regard to specific implanted surgical devices and materials is considered later and may be different from that of the general alloy class in some instances.

Influence of Composition on Stainless Steels. One of the most important phenomena associated with SCC of stainless steels is sensitization. In principle, for ferrous alloys containing 18 wt% Cr and 8 wt% Ni with carbon contents between approximately 0.03 and 0.7 wt%,

there are three phases at equilibrium at room temperature— γ -austenite, α -ferrite, and carbide ($M_{23}C_6$) (Ref 111). The transformation is so sluggish, though, that, only austenite and carbide will be observed in practice (Ref 210). Carbon is soluble in austenite up to 0.03 wt% and will precipitate out as the carbide at higher values if given enough time. Often, austenitic alloys containing more than 0.03 wt% C are heat treated at 1050 °C (1920 °F) or so to minimize the effects of cold working, and then cooled back to room temperature fairly rapidly, which largely suppresses the precipitation. However, when the supersaturated austenite is heated back up into the two-phase field ($\gamma + M_{23}C_6$), precipitation of chromium-rich carbide will take place at the grain boundaries. This creates a chromium-depleted zone that envelops the grain boundaries. Some time/temperature combinations are sufficient to precipitate the $M_{23}C_6$, but not sufficient to eliminate the concentration gradient and allow rediffusion of chromium back into the depleted zone. Since the chromium content in the vicinity of the grain boundaries is below the 12 wt% level required to passivate the material, a path of low corrosion resistance is created that can lead to intergranular corrosion and, with loading applied, to SCC. This type of structure is termed “sensitized,” and it can reduce K_{ISCC} by about 75% in certain alloy/environment combinations (Ref 111). In wrought grades of austenitic stainless steels, SCC is transgranular unless sensitization is present, in which case, it is intergranular (Ref 105). In contrast to the carbide phase, when δ -ferrite is present in austenitic stainless steels, SCC resistance is improved (Ref 211).

Use of low-carbon contents (less than 0.03%) is a recommended remedy to minimize the possibility of sensitization (Ref 111), although at long times, sensitization of type 304 stainless steel can occur even with type 304L when the carbon content is 0.015 wt% (Ref 199). It should be pointed out, though, that 304 and 304L stainless steel is not acceptable as an implant material according to modern standards and has not been used as such for many decades.

Stress-corrosion cracking of stainless steels was first recognized as a possibility in 1944 (Ref 212). Many alloying elements affect the SCC resistance of austenitic stainless steels (Ref 211). For implant alloys, the most important one of these is nickel. In boiling magnesium chloride, SCC resistance is at a minimum with about 8 wt% Ni, and increasing nickel content above that has a beneficial effect (Ref 137). Similarly, lowering the nickel content below this value also increases resistance to SCC. Molybdenum is another important element that improves SCC resistance of austenitic stainless steels (Ref 111), presumably because of its salutary effect on pitting resistance. Tests of a 19Cr-20Ni alloy in $MgCl_2$ showed SCC resistance is increased by increasing the carbon content and decreasing the amount of nitrogen in the steel (Ref 137).

Cold work is considered to be beneficial, in terms of SCC resistance, for most austenitic

stainless steels and increases time to failure in SCC tests, but it is difficult to separate out effects resulting from work hardening and those due to transformation to martensitic phases (Ref 111). Furthermore, type 316 seems to be an exception to this rule and suffers a sharp decline in cracking time when the amount of cold work exceeds about 5% (Ref 211). It is not certain, however, that this would be the case for implant-quality 316L. In addition, 316L only undergoes an austenite to martensite phase transformation at a temperature of -196°C (-321°F). Shot peening has been shown to improve SCC resistance of austenitic stainless steels (Ref 211). Stress-corrosion cracking is accelerated as grain size increases, particularly at the lower stress levels (Ref 111).

The influence of temperature on the SCC resistance of nonsensitized stainless steel is an important question for implant alloys. A generation ago, the consensus viewpoint, based on practical experience, was that stainless steels in the nonsensitized condition were immune to SCC in neutral chloride-containing environments at temperatures lower than 80 °C (175 °F) (Ref 213). The threshold reported in the literature has dropped substantially since then, however. Hoxie (Ref 214) and Truman (Ref 195) reported it was 60 °C (140 °F). Speidel (Ref 215) demonstrated that 304 stainless steel would crack at 50 °C (120 °F) in 22% NaCl and, even at ambient temperature, when in the sensitized condition. In a series of experiments involving notched and precracked 316L specimens that were highly loaded (and, in some cases, galvanically coupled to other implant materials or subjected to applied polarization levels comparable to what might be possible due to *in vivo* bioelectric effects), it was seen that at 37 °C, or 98.6 °F (internal body temperature) cracklike features developed *in vivo* and SCC crack growth occurred under laboratory conditions in Ringer's solution (Ref 5, 209, 216, 217). Transgranular SCC in nonsensitized austenitic stainless steels (304, 316, titanium-stabilized 316) has been observed at ambient temperatures when the alloys have been exposed to atmospheres above indoor swimming pools (Ref 218, 219). Similar findings of SCC in austenitic stainless steels (303, 304, and 304L) at ambient temperature, when they are not sensitized, have been reported for marine atmospheres as well (Ref 220, 221). Haselmair (Ref 222) describes a case of SCC in type 303 at ambient temperature due to chloride-laden dust in a road tunnel. In acidic chloride-containing solutions, SCC of 304 and 316 stainless steels is well documented, even at temperatures as low as -5°C (23 °F) (Ref 223–227).

In contrast to the situation for titanium alloys (described below), applied polarization enhances SCC in austenitic stainless steels tested in chloride environments as the potential increases and retards it when the potential is decreased (Ref 111). This indicates the importance of anodic dissolution processes, as opposed to hydrogen embrittlement, for the mechanism

of cracking. Therefore, the film rupture (slip-dissolution) model is the likely origin of SCC of austenitic stainless steels in chlorides (Ref 104). Highly cold-worked stainless steels can be subject to hydrogen embrittlement, however (Ref 111, 211), and may become more susceptible to crevice corrosion as well (Ref 228).

Influence of Composition on Titanium Alloys. Titanium alloys have outstanding corrosion resistance compared to many engineering alloys. This is due to the fact that titanium is reactive and very readily forms a passive film, primarily composed of TiO_2 , and other thermodynamically stable oxides, when in contact with media containing oxygen (Ref 229). This film is tenacious and self-healing (Ref 201). However, over the years, some titanium-base alloys have been shown to be susceptible to SCC in a variety of environments, including seawater and other chloride-containing environments at ambient temperature (Ref 123). Pure titanium (ASTM grades 1–3) falls in the α category and is immune to SCC in aqueous environments. This behavior depends on interstitial oxygen content, however, and when pure titanium has more than 0.2 to 0.25 wt% O, a transition from wavy to planar slip occurs. Such materials may then be prone to SCC in saline environments with a salt content equivalent to seawater (Ref 196, 230, 231).

Besides oxygen, aluminum also exhibits a negative influence on SCC resistance (Ref 232). For example, mill-annealed or duplex-annealed Ti-6Al-4V is susceptible when a loaded fatigue crack is present, particularly in thicker specimens (where plane strain conditions will be present, Ref 123). In such α/β alloys, it is the α phase that promotes SCC. Smooth or notched specimens will not exhibit SCC in neutral saline environments (Ref 233), since titanium is so resistant to pitting in such environments. Even in boiling acidic chloride-containing environments, the repassivation potential for Ti-6Al-4V, for example, is 1.7 V Ag/AgCl or higher (Ref 233). Nitrogen, hydrogen, and carbon are other interstitial elements that adversely affect α/β alloy susceptibility to SCC, and ELI grades are often specified in applications where resistance to SCC is critical (Ref 229, 234). Alloying elements that improve SCC resistance include zirconium, molybdenum, and vanadium (Ref 196, 206, 233).

For α/β alloys, the microstructure that results from thermomechanical processing exerts a strong influence on SCC susceptibility in a manner related to the grain size, volume fraction, and mean free path length of the more brittle α phase (Ref 201). The more ductile β phase acts as a crack arrestor. Particularly when β is present in a high volume fraction, or when it forms a continuous network, it will enhance resistance to SCC in saline solution. On the other hand, a fine equiaxed structure with β dispersed in a continuous α matrix (that originates from processing in the $\alpha + \beta$ phase field) will show much more vulnerability to SCC. Koch (Ref 201), Schutz and Thomas (Ref 233), and Schutz (Ref 229)

describe other α/β microstructures based on β processing or final β heat treatment that are much more SCC resistant. These different processing regimes develop different types of texture, which in turn can be related to variations in SCC resistance (Ref 196). Duplex thermal treatments have a particularly detrimental effect on SCC resistance (Ref 232). ASTM standard F 136, which applies to implant-grade Ti-6Al-4V ELI, calls for a fine dispersion of α and β phases resulting from processing in the $\alpha + \beta$ field, with no continuous α network and no coarse α platelets. This is a microstructure of the class that is more prone to SCC than the alternative microstructures described by Koch (Ref 201) and Schutz (Ref 229). Generally speaking, tests of Ti-6Al-4V have shown that K_{ISCC} will decline as σ_y increases (Ref 196). Aging of α/β alloys containing more than 5 wt% Al should not be carried out in the 400 to 700 °C (750 to 1290 °F) range, because this may form the α_2 phase (Ti_3Al), which enhances vulnerability to SCC (Ref 229).

The type of cracking observed in titanium alloys in various environments is generally related to the various regions of the V versus K curve (see Fig. 21). In stage I, cracking occurs by intergranular separation. In stage II, transgranular cleavage predominates, and in stage III, microvoid coalescence is featured (Ref 196). Fractographically, SCC of α/β alloys in aqueous environments occurs by transgranular cleavage of the α phase and ductile tearing of the β phase (Ref 229). Lowered pH tends to decrease K_{ISCC} and increase V_p . The α/β alloys exhibit a minimum in K_{ISCC} at an electrode potential of roughly -500 mV saturated calomel electrode (SCE), and the threshold will increase for potential values cathodic or anodic to this value (Ref 196, 201, 229). For Ti-6Al-4V in seawater, slow strain rate tests with cathodic polarization to a potential of -1500 mV SCE (to promote hydrogen charging) revealed that ductility is significantly decreased, but no hydride formation is involved (Ref 235). Rather, the hydrogen embrittlement observed was thought to be due to interstitial hydrogen uptake in the β phase which, when it reaches a critical level, causes lattice decohesion and brittle rupture. Excessive hydrogen uptake (500 to 600 ppm) in both α and α/β alloys, however, will lead to hydride formation and significant embrittlement (Ref 233). Increasing temperature and decreasing pH promotes absorption of hydrogen by titanium alloys.

Temperature tends to have only a minor effect on K_{ISCC} of titanium alloys, but crack velocity will increase with increasing temperature (Ref 123, 229). The activation energy for steady-state crack propagation has been reported to be 13 to 23.5 kJ/mol (Ref 123, 196). Velocity also increases as solution viscosity decreases (Ref 123). Crack velocity tends to be high and is aggravated by increasing chloride content. Velocity in neutral solutions increases with chloride concentration to the $1/6$ to the $1/2$ power for titanium alloys (Ref 123, 196, 229). As the

electrolyte becomes more acidic, K_{ISCC} declines for titanium alloys (Ref 196). For titanium-base materials that meet oxygen level standards for implant materials, the K_{ISCC} values reported for 3.5% NaCl solutions at 25 °C (77 °F) are in the 36 to 75 $\text{MPa}\sqrt{\text{m}}$ (33 to 68 $\text{ksi}\sqrt{\text{in.}}$) range for pure titanium and 45 to 51 $\text{MPa}\sqrt{\text{m}}$ (41 to 46 $\text{ksi}\sqrt{\text{in.}}$) for Ti-6Al-4V ELI (Ref 229). In aqueous environments, initiation of SCC in titanium-containing materials occurs according to the film rupture/dissolution mechanism (Ref 123, 234), while propagation is thought to be controlled by anodic dissolution or by hydrogen-assisted cracking (Ref 201, 229).

Influence of Composition on Cobalt-Base Alloys. Stress-corrosion cracking of cobalt-base alloys can occur, but this is generally only a problem at very high temperatures (at or above 150 °C, or 300 °F) in acidic chloride environments (Ref 236). Even in boiling MgCl_2 , one study found a Co-Cr alloy to be immune to SCC (Ref 237), while in another (Ref 238), where the stress level was higher and the exposure time was longer, it was seen to be susceptible. MP35N is immune to SCC, even in boiling MgCl_2 (Ref 238). Thus, it would not be expected there would be much probability for the occurrence of SCC under *in vivo* conditions. This seems to have been borne out by experience with implant alloys where few reports of *in vivo* SCC have been reported, with the exception of the Björk-Shiley heart valve (discussed later). Jones et al. (Ref 58), however, do not think that it can be said with certainty, based on their tests, that the F 75 alloy will be immune to SCC under body conditions.

Processing Aspects, Metallurgical Defects, and Microstructural Features Related to SCC. Many of the factors that affect CF also affect SCC. For example, pits can form at surface inclusions and eventually serve as nuclei for stress-corrosion cracks when the aspect ratio of the pit exceeds 10 (Ref 199). Pits shallower than this will enlarge more by uniform dissolution than by a locally focused SCC process. Also, stress raisers are of major concern regarding SCC susceptibility and crack initiation. They can arise from preexisting surface flaws, mechanical impact on the surface, or from any form of localized corrosion or surface damage such as wear, fretting, pitting, and so forth (Ref 105, 199). Cahoon and Paxton (Ref 239) examined a number of orthopedic implants from a hospital inventory before implantation and found that some 316L implants had cracks due to severe cold working that occurred due to rolling of thin sections. In later work (Ref 240), it was observed in an extensive study of 250 failed implants that 10% of the stainless steel implants did not meet the specifications of ASTM standard F 138.

Since tensile stresses are required for SCC, processes such as shot peening, which put the metal lattice at the surface in compression, can help to ameliorate SCC susceptibility (so long as they do not introduce new flaws and stress concentrations into the material).

Yield strength, presence of precipitates and second phases, segregation, and grain size are all factors that can substantially influence SCC behavior (Ref 202) and can be modified by processing and heat treatment procedures. In some alloy systems a stress level of $0.7\sigma_y$ is required for SCC to occur, while in others, it has been observed at stresses as low as 10% of the yield strength (Ref 105). A finer grain size generally reduces susceptibility to SCC, while cold work increases it in most alloy systems (Ref 204), but not in all (Ref 105). Heat treatments that provide the maximum strength for an alloy often will also create its peak vulnerability to SCC. Metallurgical variables, such as crystal structure and anisotropy, grain shape, dislocation density and geometry, stacking fault energy, and ordering, have all been linked as influences on transgranular SCC (Ref 199).

Stress-Corrosion Cracking Testing Methodology

A number of ASTM standards exist for the conduct of SCC tests (Ref 49). Relating the results of laboratory testing to failures in service, though, is not always straightforward. For example, SCC in titanium alloys can be readily demonstrated in precracked fracture mechanics specimens in a variety of environments, although failures in service tend to be rare because the great resistance to pitting of such systems makes crack initiation difficult (Ref 204). However, if the passive film is mechanically breached within a fine surface crack isolated from the bulk environment, titanium alloys can crack due to SCC, even in room-temperature chloride solutions. This occurs if the crack velocity is sufficient to prevent diffusion of the bulk electrolyte to the crack tip, which would extinguish the electrochemical reaction, by eliminating the causative microchemistry (Ref 241).

Spowls (Ref 194) points out that laboratory tests are appropriate only to service conditions where experience has shown a relevant relationship. In other words, if a specific alloy passes or does not pass a test found previously to be determinative for another alloy, this may (or may not) be significant, and a test providing reliable guidance between alloys in a given application may not provide prudent guidelines when exposure conditions differ.

Nonprecracked Specimens. The earliest SCC testing was conducted on nonprecracked specimens. A wide variety of specimen geometries have been employed (Ref 16, 137, 194, 201, 202, 205). These include notched and unnotched tension specimens, ring-stressed tension specimens, C-rings, U-bends, bent beams (with three-point, four-point, or pure bending modes of loading), tuning fork specimens, O-rings, residual stress specimens, and so forth, as described in the article "Evaluating Stress-Corrosion Cracking" in Volume 13A of the *ASM Handbook*. These usually establish constant displacement or constant load conditions, and a number

of ASTM standards can be used to guide such testing, for example, G 30, G 35, G 36, G 38, G 39, G 47, G 49, and G 58. Most of these configurations load the sample elastically, though the U-bend involves a plastically deformed test specimen. For notched or unnotched specimens tested in tension or bending, the data are usually presented as a time to failure versus stress curve (Fig. 22). The time measured includes t_{inc} (see below) plus the time required to progress through the three crack propagation stages.

Fracture Mechanics Approach. As with CF, the fracture mechanics approach has been found to be very useful in SCC studies. A difference between the two, though, is that even when there is a preexisting crack, for SCC there will be an incubation time t_{inc} required before cracks begin to propagate, and t_{inc} may represent a considerable period of time (Ref 242). Such effects also have been observed for implant alloys (Ref 216). The incubation time is necessary to establish local crack tip chemistry and electrochemical conditions that are severe enough for crack propagation to start.

As with the nonprecracked specimen approach, a plethora of different specimen types have been used to implement SCC testing based on fracture mechanics methods. Almost all of the plane strain fracture toughness specimens have been adapted to SCC testing (Ref 194). These include designs that have K increasing as cracking proceeds, decreasing with crack propagation, or constant with crack extension. The specimen dimensions, especially the thickness, should be such that predominantly triaxial (plane strain) conditions are created, so that plastic deformation is restricted to a very small zone in the crack tip vicinity (Ref 205). This requirement is similar to that for CF specimens discussed previously, and further detail is given in ASTM standard E 1681. Practices for preparing precracked specimens are covered in ASTM standard E 399. These include cracked plates, circumferentially cracked round bars, bending specimens, double cantilever beams, and others. Loading is accomplished via tensile testing machines, loading wedges, or three-point, four-point, or cantilever bending. These samples are more fully described in various works (see, for example, Ref 137 and 194).

Though use of fracture mechanics specimens eliminates uncertainty and variability associated with the crack initiation process, it should be pointed out that, for very small cracks, LEFM (Eq 23) predicts stresses that are unrealistically high. So LEFM results will not necessarily completely extrapolate back to the results with smooth specimens (Ref 205).

Slow strain rate (SSR) techniques have largely supplanted constant stress tests in recent years (Ref 199) because they are quicker and, also, because it has been shown that the crack growth rate is a function of the applied strain rate. The idea here is that a series of tensile tests to failure are conducted with standard tensile specimens (ASTM E 8) contained in an appropriate environment of interest (Ref 15). The

strain rates used span orders of magnitude, but all have rather low values. This approach was inspired by the development of mechanistic models to explain the SCC process, most of which, as has been shown, involve crack tip plastic microstrain and passive film rupture. In the SSR test, when the yield stress is exceeded, plastic deformation occurs that assists in SCC crack initiation (Ref 137). Guidelines for implementing this method are found in ISO standard 7539-7, as well as in ASTM standard G 129.

Figure 23 shows the typical ductility (and ductility ratio) versus strain rate response for two materials vulnerable to environmentally induced cracking in an aggressive environment. The ratio is equal to the value of the ductility parameter in an aggressive environment divided by its value in an inert environment. Alloy A can suffer from hydrogen-induced cracking, and alloy B is susceptible to SCC. For each material in an inert environment, there is only a modest influence of strain rate on specimen ductility. For alloy A, though, when the strain rate is sufficiently slow in an environment causing HE, the reduction of area diminishes steadily until it reaches a plateau value at very low strain rates. For SCC (alloy B), there is a critical value of strain rate where the reduction of area is a minimum. This minimum is characteristic of the alloy system/environment/potential/temperature combination being tested, and the most severe strain rate must be determined in each case (Ref 194, 243).

The critical strain rate maintains a delicate balance among deformation, diffusion, anodic dissolution, and passive film formation (Ref 243). Generally, the lower the SCC crack velocity, the lower the critical strain rate will be. For titanium alloys and stainless steels in chloride solutions, the critical strain rates are respectively reported to be 10^{-5} and 10^{-6} s^{-1} (Ref 15). One study with stainless steels, however, has indicated that lower rates may be needed in some cases (Ref 244). In 100 °C (212 °F) 20% NaCl, the strain rate had to be reduced to $7.87 \times 10^{-8} \text{ s}^{-1}$ before SCC was evident in 304 stainless steel. In 10% NaCl the rate had to be lowered to $7.09 \times 10^{-9} \text{ s}^{-1}$. In 3.5% NaCl, when the sample was polarized anodically by 45 mV,

Fig. 22 Time to stress-corrosion cracking failure versus applied stress

the strain rate needed was also $7.09 \times 10^{-9} \text{ s}^{-1}$. It is possible that at the lower chloride contents and temperature characteristic of *in vivo* conditions, an even lower rate might be required.

At the beginning of the SSR test, the strain rate is well characterized and controlled; but when cracking starts, the strain is mainly concentrated at the crack tip, where the actual effective rate of straining is unknown (Ref 194). Hishida et al. (Ref 245) provide mathematical analyses of the SSR test that allows the effects of pure mechanical deformation, crack growth, and anodic dissolution to be separated. For SSR testing, a plot of crack velocity versus strain rate will show a threshold effect, a plateau velocity, and an increase when large strain rates are used (Ref 199, 246). This behavior is similar to that shown in Fig. 21 for the stress-intensity dependence. The susceptibility to SCC in a SSR test is maximized at strain rates corresponding to the plateau velocity.

This method has been extended to include bending tests, as well as notched and precracked specimens. Another variant of dynamic testing applied to SCC involves step loading. Here, both precracked and smooth samples can be used to rapidly identify the stress or stress-intensity thresholds for SCC (Ref 202). Another variant is the constant extension rate test (CERT), sometimes referred to as a straining electrode test (Ref 137). This is similar to the SSR method, except that extension rate rather than strain rate is controlled.

Slow strain rate tests have the advantage that they are quicker than other types of SCC testing, generally produce less data scatter, and the test always ends with the mechanical failure of the specimen. This eliminates samples that do not fail because they are loaded below K_{ISCC} (Ref 199). After the test, the sample gage section is observed to note any secondary cracking that may be present (Ref 201), and the fracture surface is also examined for evidence of SCC. The ductility minimum for SCC occurs because, when the strain rate is much larger than the critical value, the samples will fail by ductile fracture, while, when it is very low, repassivation

will occur (preventing the corrosion necessary to drive the SCC process). Besides reduction of area, other variables that change due to SCC (compared to a nonsusceptible condition) include time to failure, maximum nominal stress, percent elongation, and area under the stress strain curve (Ref 15, 16, 201). Because effects not related to SCC are also present in an SCC test, the general practice is to also test the material of interest in an inert environment (air or oil, for example). The ratio of the value of a property in the corrosive medium to that found under inert conditions provides an index of the resistance to SCC. The more the ratio departs from unity, the more vulnerable to SCC the material will be (Ref 205). Abe et al. (Ref 247) defined another susceptibility index as the ratio of the area associated with SCC fracture to that associated with mechanical fracture. They found that this index is well time-correlated with failure observed with constant load SCC tests. Daniels (Ref 244), on the other hand, compared SSR, U-bend, and constant stress specimens made of 304 stainless steel and found differences among the test methods. As with other types of SCC testing, electrode potential is an important variable. Applied polarization, changes in environmental chemistry, and galvanic coupling can shift the potential of the alloy into a region conducive to SCC (Ref 243).

The SSR technique has been seen to be very useful when ranking various alloys as to their resistance to SCC in a given environment or for investigating the influence of metallurgical variables on the susceptibility of a given material (Ref 137). However, use of SSR data to predict crack propagation rates for actual service conditions is problematic.

Accelerated SCC Tests. Because of the very long time periods that can be involved in SCC experiments, particularly using either smooth or precracked fracture mechanics type specimens, there has been interest in finding means for accelerating these tests, but in ways that can be extrapolated to the service conditions of interest. This is inherently difficult due to the complex compositional, electrochemical, metallurgical,

and mechanical interactions involved in SCC (Ref 205). As pointed out previously, severe stress conditions lower the incubation time for crack initiation and increase velocities at least up to the plateau region. Crack velocities have been shown in some circumstances to be thermally activated and to follow an Arrhenius equation (Ref 248):

$$V = A \exp(-Q/RT) \quad (\text{Eq 25})$$

where A is a pre-exponential factor, R is the gas constant, T is the absolute temperature, and Q is the activation energy for SCC (which is related to a solid-state diffusion process). Thus, elevating the temperature can be used to substantially increase the cracking rate and lower the time to failure. The activation energy in the SCC case, though, depends on stress intensity and decreases with K^2 . This type of accelerated testing approach would only apply when one process controls cracking kinetics over the whole range of test temperature conditions and throughout the service temperature range to which the data are extrapolated. Use of more chemically severe testing conditions, such as employing boiling MgCl_2 to get some insight into susceptibility of SCC in milder chloride-containing environments (such as seawater or *in vivo* electrolytes), provides a qualitative means for test acceleration. This is a particularly popular test for austenitic stainless steels (Ref 111). It is so commonly used that an ASTM standard has been developed (G 36) to standardize the testing protocol. The MgCl_2 test has been in use since the 1940s. A relatively new standardized test (ASTM G 123), approved in 1994, involves exposure to a boiling acidified NaCl solution. This test is less severe than the MgCl_2 test, but is thought to be better correlated with NaCl service environment experience (Ref 211). Over and beyond the uncertainties discussed previously regarding the difference in temperature, uncertainties as to how changes in bulk electrolyte concentration, pH, and so forth, affect the microchemistry at the crack tip have so far precluded development of a precise means for predicting behavior in mild environments from behavior measured under extreme conditions.

With precautions, however, it does appear that a series of tests using boiling MgCl_2 , 5% HCl at 37°C (98.6°F), and 37°C Ringer's solution can allow meaningful accelerated testing to occur for implant alloys (Ref 209, 216, 217). Using fracture mechanics specimens, increasing temperature was seen to substantially lower K_{ISCC} , raise V_p , and lower the incubation time required to initiate propagation from a precrack. An activation energy for SCC of 316L stainless steel was computed from this work to be 51.0 kJ/mol . This is consistent with the range observed for various austenitic stainless steels in chloride-containing media (Ref 249–252). Since these environments and tests had different pH and Cl^- concentration values, as well as differences in polarization conditions, it was pointed out (Ref 216) that the alternative procedure of Speidel

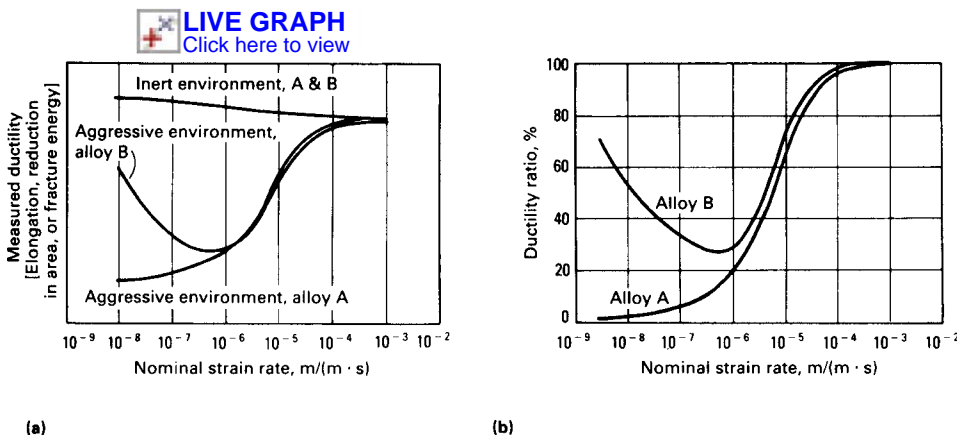

Fig. 23 Influence of strain rate in slow strain rate testing. (a) Ductility parameters versus strain rate in inert and aggressive environments. (b) Ductility ratio versus strain rate for materials susceptible to hydrogen embrittlement (alloy A) or stress-corrosion cracking (alloy B)

(Ref 215), $\log V_p$ versus T regression, could be used. For 316L it was found that:

$$\log V_p = 2.037 \times 10^{-2} T - 10.31 \quad (\text{Eq 26})$$

when V_p is in units of m/s and T in $^{\circ}\text{C}$. It was seen that, for both 316L and Ti-6Al-4V ELI, incubation time t_{inc} was a strong function of stress intensity and decreased as K increased:

$$t_{\text{inc}} = C \exp(-AK) \quad (\text{Eq 27})$$

where C and A are constants depending on the material, environment, and polarization conditions investigated.

It is conceivable that an accelerated testing approach could be used for CF studies also, since it has been shown that fatigue crack growth velocities in austenitic stainless steels increase as temperature increases (Ref 31).

Findings from SCC Laboratory Testing

A number of studies have attempted to simulate, in the laboratory, conditions that might cause SCC in the *in vivo* environment. Due to the susceptibility of stainless steels to cracking in chloride-containing environments, most of this work, though not all, has focused on 316L. A variety of results have been obtained, depending on the testing methodology and what *in vivo* variables are simulated. These findings are reviewed in this section. Because of the ability to better control variables in the laboratory, as opposed to in an animal or clinical study, a particularly important motivation for SCC testing in the laboratory is that the loading condition can be set to ensure a static tensile stress component is applied to the test specimen. As pointed out previously, under *in vivo* conditions, the loading applied is often unknown, and fractographic evidence may be subject to ambiguous interpretation, in certain situations, as to whether the cracking observed is due to SCC or CF.

Stainless Steels. Gilbertson (Ref 253) tested specimens of vacuum melted 316L (316L VM) and 304 stainless steel in four-point bending in acidified Ringer's solution (pH 2 to 3) at 66°C (151°F). Stresses used were both above and below σ_y . Cracking was noted in 304 after about 800 h of exposure, while the 316L samples did not exhibit SCC, even up to 15,000 h of exposure.

Jones et al. (Ref 58) performed SSR tests on specimens of 316L and various TRIP steels at a strain rate of $4.4 \times 10^{-6} \text{ s}^{-1}$ in 37°C Tyrode's solution and in room temperature air. No evidence of SCC was seen for either annealed or cold-worked 316L. The ductility was lower for several of the TRIP steels; however, fractographic signatures of SCC were absent.

Sheehan et al. (Ref 254) tested 316L in aerated, lactated 37°C Ringer's solution using SSR methods at strain rates in the 10^{-5} to 10^{-7} s^{-1} range. No difference in tensile strength or ductility properties were noted as a function of strain

rate, and it was concluded that no SCC susceptibility was evident. This was also the case when the solution was acidified to pH 2. They also tested Schneider intramedullary nails in three-point bending (where the highest stress in the sample was at the yield stress) for 6 months, as well as other 316L samples in cantilever bending for 8 months. No evidence of SCC was found using either of these experimental protocols. These investigators also performed CF tests in Ringer's solution and observed significant secondary cracking which, in some cases, produced crack branching features (in situations of high ΔK and rapidly advancing cracks) that appear quite similar to the branching characteristically observed with SCC. As pointed out previously, it appears that, without knowing the loading history of an implanted device, it is difficult to determine for certain whether a branched crack pattern is a signature of SCC or represents CF that occurs under a certain restricted set of conditions. However, if a secondary fatigue crack is opened up and examined fractographically, it will exhibit striations.

Bundy et al. (Ref 5) noted extrapolating results of SCC tests in 37°C physiological saline solution to predict *in vivo* performance tacitly assumes the organic biomolecules present in the body, as well as bioelectric effects *in vivo*, play no role in SCC under clinical conditions, assumptions that had not been tested experimentally. This observation was based on comparison of literature (on SCC from laboratory tests) with clinical reports and animal experiments conducted by them and others (discussed in the next section describing *in vivo* and retrieval studies). In addition, it was noted that knowledge of the loading patterns to which retrieved implants had been subjected was difficult to obtain. A series of laboratory experiments were, therefore, conducted to examine the effects of applied stress and applied electrical polarization on the SCC behavior of implant materials, 316L among them (Ref 5, 209, 216, 217).

In the first study (Ref 5), three-point bending of smooth samples was used. Three different maximum stress levels were used with different samples— $0.8\sigma_y$, σ_y , and σ_{uts} . Control samples, that is, those subjected only to applied stress, were exposed to 37°C Ringer's solution for 53.5 weeks. Other specimens in this same environment for 38 weeks were stressed to these same levels, but also had a +100 mV potential applied to them. Consistent with the other laboratory studies cited previously, no cracklike features were observed in the control samples, no matter how highly stressed. Some pitting was observed, increasing in severity as stress level increased. On the other hand, cracklike features were observed for the polarized specimens at and above σ_y , implying that *in vivo* bioelectric activity might spur SCC in highly loaded samples. The biochemical aspect of the hypothesis that *in vivo* chemical and electrical conditions differ from those in 37°C physiological solution was not examined, due to the multiplicity of

possible agents and the chemical specificity often associated with SCC processes. However, the cracklike features observed *in vitro* were not as severe as those found *in vivo* (see the next section) for shorter exposure times, which could be consistent with a further increment of SCC susceptibility being conveyed by a biochemical agent (or more damaging *in vivo* bioelectric effects than those simulated in the laboratory).

In the latter three publications from this laboratory (Ref 209, 216, 217), a more controlled fracture mechanics approach was used with wedge-loaded double cantilever specimens to quantify threshold stress intensity K_{ISCC} , steady-state plateau crack propagation velocity V_p , and incubation time for initiation of crack propagation, t_{inc} . Three test environments were used: boiling MgCl_2 to quickly gage SCC susceptibility in chloride media, 5% HCl at 37°C to determine susceptibility in chloride media at body temperature, and 37°C Ringer's solution to more closely simulate the *in vivo* situation. In some specimens, applied polarization was employed as well. Besides the +100 mV regime, as used in the investigation with smooth samples to simulate the magnitude of possible bioelectric effects, two additional regimes of polarization were used for the tests in Ringer's solution. One involved polarization to break down the passive film, followed by potentiostatic polarization to prevent repassivation (corresponding to a current density of about $10 \mu\text{A}/\text{cm}^2$). The second regime involved galvanostatic polarization at this current density level without the initial breakdown step. These regimes were regarded as more likely to spur SCC, if it were governed by a film rupture/repassivation mechanism. To gain further insight into the influence of potential, both anodic and cathodic direct current (dc) potentials were applied to the specimens tested in magnesium chloride. In an extension of these studies, a square wave alternating current (ac) signal was superimposed on a dc bias for 316L in Ringer's solution (Ref 255).

For unpolarized 316L, V_p values were 8.5×10^{-8} and $4.5 \times 10^{-10} \text{ m/s}$ in MgCl_2 and HCl solutions, respectively. K_{ISCC} values were $9.5 \text{ MPa}\sqrt{\text{m}}$ ($8.6 \text{ ksi}\sqrt{\text{in.}}$) in the 44% MgCl_2 environment at 154°C (309°F), and $70 \text{ MPa}\sqrt{\text{m}}$ ($64 \text{ ksi}\sqrt{\text{in.}}$) in 5% HCl at 37°C . Thus, cracking is enhanced when the temperature is higher and the chloride concentration is greater, as previously pointed out. The V_p and K_{ISCC} values in MgCl_2 are similar to those seen by the individuals who have tested other austenitic stainless steels in this environment (Ref 215, 249, 256–258). Even at high stress intensity, no SCC was observed after 575 days of exposure in Ringer's solution (consistent with the result of Gilbertson, Ref 253, mentioned earlier). Similarly, for two of the polarization regimes, no SCC was noted for the conditions used in the test. For the polarization method, where the passive film breakdown step was used, SCC did occur in Ringer's solution. The incubation time was

168 h, and the crack propagation velocity was 2.4×10^{-10} m/s. For the ac waveform, SCC was also observed, with V_p being 1.16×10^{-10} m/s. Here, the incubation time was 1272 h, compared to 168 h for the dc polarization. For the tests in MgCl_2 , anodic polarization slightly increased V_p and modestly increased K_{ISCC} . Cathodic polarization seemed to inhibit SCC, raising K_{ISCC} , while lowering V_p . This is consistent with an SCC mechanism where the cracking rate is controlled by competitive adsorption of OH^- and Cl^- ions on the surface. It is consistent with data from smooth specimens of 304 stainless in the same environment, showing that time to failure decreases as potential increases (Ref 104). The greatest influence of polarization in this environment was on t_{inc} . Anodic polarization reduced the incubation time by about an order of magnitude. These results indicate that SCC of 316L stainless steel can occur in Ringer's solution at body temperature when certain very severe conditions exist: a preexisting crack, high stress intensity, and a disrupted passive film that does not repassivate.

More recently, Roach et al. (Ref 259) and Zardiackas et al. (Ref 260) have conducted SSR tests on both 316L and newer implant stainless steels, 22Cr-13Ni-5Mn and Bio-Dur 108, a low-nickel-content stainless steel. They used smooth and notched samples tested in distilled water and Ringer's solution at 37 °C. They computed the percent elongation ratio (PER) and the reduction of area ratio (ROAR), that is, the property value in Ringer's solution divided by that in distilled water, for these tests. Using a criterion of SCC occurrence when either ratio falls below 0.9, no evidence of SCC was observed in these experiments (the lowest value was 0.92). Significant notch sensitivity was observed for the stainless steels, however. The reduction of area for notched compared to smooth specimens was only 48.4%, 28.5%, and 23.5% for 316L, Bio-Dur 108, and 22Cr-13Ni-5Mn, respectively. Fractographically, only the Bio-Dur alloy showed a fracture mode consistent with SCC in some stainless steels (areas of brittle cleavage mixed in with dimpling) (Ref 260), yet this same morphology was present whether testing was in air, distilled water, or Ringer's solution. As a result, this fractographic pattern could not be construed as evidence of SCC in this case.

To the authors' knowledge, there has been only one laboratory study of SCC that was aimed at simulating a situation pertinent to clinical dentistry—Sutton and Sanders (Ref 261). Since rubber dam clamps have been known to fail in service (see the retrieval section below), they tested stainless steel rubber dam clamps that were subjected to various cleaning/autoclaving regimes and exposed to various NaOCl (sodium hypochlorite bleach) solutions. Corrosion spots occurred on the surfaces, and both intergranular and transgranular SCC were reported.

McEvily (Ref 137) presents various types of experimental data that relate to the susceptibility to SCC of austenitic stainless steels in aqueous and saline environments. For example, it is

shown for 304 that the Cl^- threshold concentration to cause SCC decreases as the oxygen level increases.

Titanium-Base Alloys. Bundy et al. (Ref 5) also examined the SCC behavior of Ti-6Al-4V ELI. The findings were similar to those noted for 316L, discussed previously. No cracklike features were noted at any stress level for controls at 53.5 weeks of exposure. For the anodically polarized samples at 38 weeks, however, cracklike features were observed for the samples that were maximally stressed at or above σ_y , though the surface attack was less marked than for 316L. The cracklike features were more numerous at σ_{uts} than at σ_y .

Their fracture mechanics studies (Ref 209, 216, 217) also involved SCC testing of the Ti-6Al-4V ELI alloy. For this biomaterial, the crack propagation velocity was much higher than for 316L. In this titanium-base alloy, V_p values were 8.0×10^{-5} and 2.4×10^{-9} m/s in the MgCl_2 and HCl solutions, respectively. The SCC threshold stress intensities of this alloy were, respectively, 22.6 and 53.9 $\text{MPa}\sqrt{\text{m}}$ (20.6 and 49 $\text{ksi}\sqrt{\text{in.}}$) in MgCl_2 and HCl . Thus, compared to 316L, the titanium-base material has a higher K_{ISCC} in magnesium chloride, but a lower one in 5% HCl . Stress-corrosion cracks in Ti-6Al-4V ELI, however, will propagate much faster than in 316L. Although from the data above it would appear that in the 37 °C environment, the titanium alloy is more susceptible to SCC than is 316L, the incubation time evidence points to the opposite conclusion. It took the cracks in the titanium alloy more than a year to begin growing. For 316L, the initiation time was about 1.5 months. So, a more accurate interpretation is that the titanium alloy is more resistant to crack initiation; however, once a crack forms, it propagates more rapidly in Ti-6Al-4V ELI compared to 316L.

Mishra and Davidson (Ref 262) used the SSR technique to test Ti-6Al-4V and three surface preparations of an experimental alloy, Ti-13Nb-13Zr, at a strain rate of $4 \times 10^{-6} \text{ s}^{-1}$ in 38 °C (100 °F) Ringer's solution. No evidence of SCC was found in this work.

Zardiackas et al. (Ref 263) have tested some of the newer titanium-base implant alloys in 37 °C Ringer's solution and aerated distilled/deionized water using the SSR approach on smooth samples. They examined a spectrum of titanium alloys representing α , α/β , and β microstructures: CP Ti grade 4 (ASTM F 67), Ti-6Al-4V ELI (ASTM F 136), Ti-6Al-7Nb (ASTM F 1295), and β -annealed Ti-15Mo (ASTM F 2066). The CP Ti was cold worked, while the others were in a heat treated condition. The materials were tested using a constant extension rate of 10^{-5} mm/s. They determined the PER and ROAR ratios and found no evidence of SCC using the criteria of a positive result when the ratio is ≤ 0.9 , nor from SEM fractographic examination. The lowest value observed was $\text{PER} = 0.94$ (for Ti-6Al-4V ELI).

Williamson et al. (Ref 264) extended this study by also measuring notched samples

according to the ASTM G 129 (SSR testing) experimental protocol. The results of the two investigations were similar. For the notched specimens, no SCC was seen either. Here the lowest ratio observed was $\text{ROAR} = 0.92$ for the CP Ti grade 4. Again, no differences in the SEM appearance of the fracture surfaces from samples tested in Ringer's solution or distilled water were observed.

Zardiackas et al. (Ref 159) followed the same basic experimental protocol (as for the studies mentioned above) for CP Ti testing to investigate the influence of anodization on the SCC process. Both smooth and notched specimens were tested. For all test conditions examined, the only ratio below the 0.9 SCC immunity criterion was the ROAR for notched samples. Here, the ratio was about 0.84, with anodized samples showing slightly less SCC susceptibility than the controls. Fractographic observations also showed no evidence of SCC, except for secondary cracking on the notched specimens. Thus, anodizing was found to have no tendency to increase SCC susceptibility, and CP Ti was seen to be immune to SCC, except when a severe notch was present.

A number of studies have examined the SCC behavior of titanium alloys in a 3.5% NaCl solution with salinity similar to seawater. Hsiao et al. (Ref 14) measured crack tip pH to be 2 or below, a situation conducive to cathodic evolution of hydrogen. They hypothesize that hydrogen plays a major role in SCC crack propagation of titanium alloys in neutral saline solution. McEvily (Ref 137) presents SSR data showing that Ti-6Al-4V is susceptible to SCC in this environment at 25 °C (77 °F), and its K_{ISCC} value declines as the oxygen content of the alloy increases. Also, he presents data indicating titanium alloys (including Ti-6Al-4V) will experience an increased SCC crack propagation velocity as applied potential is increased. McEvily (Ref 137) presents experimental data showing, as the aluminum content is increased, less oxygen in the lattice can be tolerated to maintain good SCC resistance. Additionally, he shows resistance to SCC will decline as the hydrogen content of the material is increased.

Consistent with the work of Hsiao et al. mentioned previously, Yokoyama and his coworkers have conducted several studies that indicate titanium-base implant alloys, particularly those used in dentistry, are susceptible to hydrogen embrittlement under conditions relevant to *in vivo* use. For example, Ogawa et al. (Ref 265) showed that β titanium is subject to hydrogen absorption and embrittlement in acidified phosphate fluoride solution and claim this is related to delayed fracture. Yokoyama et al. (Ref 266) found that hydrogen embrittlement occurs in the superelastic form of NiTi in fluoride solution. Based on this, they suggest that one reason titanium and its alloys fracture in the oral cavity is due to hydrogen absorption in fluoride solutions used as prophylactic agents. Similarly, for the work-hardened form of Nitinol, they

demonstrated hydrogen embrittlement in acidified phosphate fluoride. This solution simulates fluoride-containing toothpastes and prophylactic agents (Ref 267). Shabalovskaya et al. (Ref 268) have also found chemical etching of Nitinol wires in a hydrofluoric/nitric acid (HF/HNO₃) solution, followed by aging in boiling water, will produce a cracked surface similar in appearance to SCC. Conceivably, residual stress in the wires could be involved here. Topical fluoride solutions at 37 °C (98.6 °F) have been shown to cause SCC of CP Ti U-bend specimens after 5 days of exposure (Ref 269).

Cobalt-Base Alloys. There have been fewer laboratory investigations of the SCC susceptibility of cobalt-base implant alloys than for the stainless steels and titanium alloys. In the study mentioned previously in the stainless steel section, Jones et al. (Ref 58) also tested Vitallium (ASTM F 75) using the SSR method in Tyrode's solution and in air. No evidence of SCC was observed. Kumar et al. (Ref 270) performed SSR tests on F 75 material that was cast, wrought, or had been processed using powder-metallurgy techniques. Stress-corrosion cracking was demonstrated in all material conditions in boiling 30% MgCl₂, although more so for the more ductile powder-metallurgy and wrought materials than for the cast alloy. No SCC was evident in Ringer's solution at body temperature. Similarly, Mishra and Davidson (Ref 262) used SSR methods to investigate the ASTM F 799 Co-Cr alloy in 38 °C (100 °F) Ringer's solution and also observed no evidence of SCC.

Edwards et al. (Ref 271) tested an F 75 alloy using the SSR method, while potential was applied to the sample exposed to a 37 °C Ringer's solution electrolyte. The tests at anodic potentials gave no indication of SCC, but the samples that were cathodically polarized suffered from a considerable degree of hydrogen embrittlement. Tests using controlled hydrogen charging also confirmed the susceptibility of the alloy to hydrogen embrittlement. The cathodic potentials used by the investigators in these tests were based on the amount of cathodic shift the alloy naturally experiences when a crevice situation is established.

Findings from *in vivo* Testing and Retrieval Studies Related to SCC

There have been a number of pertinent studies related to the occurrence of SCC under *in vivo* conditions since Zapffe's first report from more than a half century ago of a failure analysis of a fractured 316 fracture fixation plate (Ref 272). These have included both observations stemming from examination of retrieved implants, as well as animal studies conducted under more controlled conditions. Another early report of *in vivo* SCC was provided by Bechtol et al. (Ref 273). Galante and Rostoker (Ref 274) tested several alloys in the back muscles of rabbits for an exposure period of one year. They used U-bend type specimens made from pure titanium,

Ti-6Al-4V, 316L, Vitallium, and Zircaloy-4 (which is a zirconium-base alloy containing 1.5 wt% Sn, 0.15 wt% Fe, and 0.1 wt% Cr). The stress in the vicinity of the U-bend exceeded σ_y . The specimens also had a third piece in the spot weld area to create crevice-corrosion conditions. Unlike an examination of a retrieved implant, where the loading history and residual stress level is unknown and where, as previously pointed out, similar fracture features may be characteristic of SCC or CF, a crack or fracture in this type of specimen would have only one possible cause (SCC). This sort of approach can separate out cracking due to SCC from that caused by CF. After the exposure period was up, the specimens were removed, cleaned, and examined at 100 \times . No cracking was observed with these samples, although pitting was seen in some cases. All specimens were surrounded by a fibrous encapsulating membrane. In another paper, these investigators mentioned what they say is a clear case of SCC in a stainless steel prosthetic device (Ref 275).

Hughes and Jordan (Ref 175) conducted a study of several broken retrieved implants. These were mostly stainless steel, although an implant was made of titanium in one case. Examination of these failed implants revealed the fractures were caused by CF, overload, and, in one case of a stainless steel implant in the sensitized condition, by SCC. In the same time period, Rose et al. (Ref 276) described a case of SCC of a Vitallium nail-plate assembly. Gray (Ref 277) reported on a failed intramedullary pin and failed bone screws fabricated from 316L. The intramedullary pin failed by LCF originating at a stress concentration remaining from centerless grinding that had not been removed by an electropolishing treatment. One of the screws failed by SCC and the other by overload failure during removal. Dumbleton and Miller (Ref 6) describe a case of SCC in a retrieved implant using a Garber nail and Thornton side plate made of 316L. The patient was nonweight-bearing and not ambulatory, but the side plate fractured anyway. The cause of the SCC was determined to be stresses induced because locking nuts were improperly seated at surgery.

Lisagor (Ref 178) describes a case of a retrieved type 316 stainless steel implant that had been plastically deformed, a situation that created residual tensile stresses, which ultimately led to failure by SCC after 15 months *in vivo*. Cyclic loading was involved only in that it may have prevented repassivation (and actually could have lowered the stresses causing stress-corrosion crack growth). In this case, a mixed-mode (intergranular/transgranular) failure was observed. White et al. (Ref 8) investigated several cases of failed stainless steel implants (a screw and plate from a Smith-Petersen nail-plate assembly, and a rush rod). They saw that most of the fracture surface was attributable to fast fracture (indicative of high stresses in the implants), but the initiation region displayed fractographic features that indicated initial crack propagation was due to a combination of SCC,

CF, and HE. The cracks originated in an area where pitting or crevice corrosion was occurring. Bombara and Cavallini (Ref 278) studied several failed Küntschers nails. They were made from 316L, but contained excessive amounts of sulfide inclusions. Pits initiated at these sites, mainly along the exposed longitudinal cross sections of the nail, and cracks proceeded via transgranular SCC.

Bandyopadhyay and Brockhurst (Ref 279) investigated two cases of failed 316L hip prostheses. As was seen in the work of Lisagor (Ref 178) mentioned previously, they observed a mixed intergranular/transgranular mode of SCC failure. Sandborn et al. (Ref 280) describe a case of a failed unicompartmental knee implant femoral component made of cast stainless steel. The material was found to contain a high inclusion content and was characterized by a marked inhomogeneity of grain size, with some grains being so large as to span the entire width of the implant. The implant had been placed incorrectly, which heightened the stresses in the implant. The failure was mainly caused by an intergranular fatigue fracture (originating in an area of wear) that may have been due to alloying element segregation at the grain boundaries. However, there were also pits and scratches on the side of the implant experiencing tensile loading, and stress-corrosion cracks emanated from some of the pits.

Syrett and Davis (Ref 281) performed an animal study in which bone plates made from a TRIP stainless steel (12.5 wt% Cr, 7.27 wt% Ni, 3.88 wt% Mo, 0.29 wt% C, minor amounts of Mn, Si, P, and S, balance Fe) were implanted in rhesus monkeys. The animals were sacrificed at 100 to 104 weeks, and SCC was observed in 50% of the implanted plates. A coupon of the same material implanted in rabbit muscle for the same period of time also exhibited SCC, even though this is a low-stress site. It was thought that the cause of failure in this case was residual stresses due to polishing of the implanted material.

Bundy et al. (Ref 5) performed an *in vivo* investigation in which ring-stressed tension samples were used where the stress level could be controlled in a notched test specimen. They tested specimens where both the ring and the stressed sample were made from the same alloy, as well as situations in which dissimilar metals were used for the ring and notched specimen to create galvanic coupling conditions. Test materials in the first category included 316L, Ti-6Al-4V ELI, and MP35N. Test conditions where galvanic coupling was employed included 316L (specimen)/MP35N (ring) and Co-Cr-Mo (specimen)/Ti-6Al-4V ELI (ring). The stress-ring samples were loaded so the nominal stress in the test sample in the notched area was σ_y . The specimens were subcutaneously implanted into the backs of New Zealand white rabbits. The exposure periods used range from 33 to 114 days. MP35N showed no tendency to exhibit cracking behavior. Both 316L and Ti-6Al-4V ELI, after 114 days, showed surface changes consisting of

pitting, possible crack initiation sites, or crack-like features, when viewed at much higher magnification than that used by Galante and Rostoker (Ref 274). A Co-Cr-Mo sample that had been accidentally overloaded and cracked before implantation showed no growth of the crack after 33 days *in vivo*. In another specimen, there was plastic deformation due to the loading. Although only stressed to σ_y , apparently the very coarse-grained cast structure had some surface grains oriented favorably for slip. For this sample, after 73 days of exposure, a crack was observed that had nucleated in a heavily slipped area.

Bundy (Ref 282) has summarized the results of his investigations described previously and listed conditions under which representative alloys from the three main classes of metallic implant materials will and will not undergo SCC *in vivo* and *in vitro*. These conditions involve stress level, exposure time, galvanic coupling condition, stress-intensity level, electrical potential and polarization condition, and presence of a notch or precrack.

Though the vast majority of reports from retrieval studies where SCC is implicated concern orthopedic applications, there are scattered reports of SCC occurring in other sorts of applications as well. To the authors' knowledge, there are only three reports of SCC that are pertinent to clinical dentistry. Jedynakiewicz et al. (Ref 283) describe 21 fractures of nickel-plated 0.8 wt% plain carbon steel dental dam clamps that failed intraorally. The fractures were determined to arise from SCC as a consequence of HE that occurred when phosphoric acid etching procedures were being used clinically. Odén and Tullberg (Ref 284) found intergranular cracks in a gold casting alloy used as a crown cemented onto an amalgam core. The stresses were thought to arise from delayed expansion of the amalgam, expansion as a consequence of amalgam corrosion, or overloading. Either segregation of alloying elements at the grain boundaries or diffusion of mercury to the grain boundaries were thought to be involved in the SCC process. Mercury also can have a deleterious effect on the fatigue life of a platinized gold casting alloy (Ref 285). Yokoyama et al. (Ref 286) analyzed a CP Ti screw in a dental implant system that had fractured, and found the cause to be hydrogen absorption. This led to the controlled studies of hydrogen embrittlement of titanium implant alloys that were described in the previous section.

Brantigan et al. (Ref 212) provide reports of two SCC cases pertinent to thoracic surgery. These involved stainless wires that had fractured. Kossowsky et al. (Ref 287, 288) describe an SCC failure of an aneurysm clip used intracranially. The patient died following the rupture of the aneurysm. The material used to manufacture the clip was type 17-7PH stainless steel.

There has been only one cardiovascular application where *in vivo* SCC has been reported, the Björk-Shiley valve. This case has received considerable attention because it can lead to a

fatal outcome. Many hundreds of these prosthetic valves have shown fracture in the weld area of the tungsten inert gas welded leg struts on the downstream side (Ref 289–291). These valves have a ring made of Haynes 25 alloy (also known as HS-25, basically the F 90 alloy) and a carbon occluder. The individual retrieval, or *in situ* radiographic studies cited previously, shows the single leg strut fracture (SLF) frequencies range from about 4 to 40%, depending on valve design, valve location, valve size, test method, and patient age group.

At the end of 1995, 575 such failures had been reported, 0.67% of the total number of valves implanted, a value considered to be significantly underestimated, since autopsy rates are low. The manufacturer's risk analysis, using actuarial data (Ref 290), found the annual probability of valve failure per year to be 0.22 to 2.52%. A significant number of fatalities have occurred due to this SLF problem. Xiao and Appleby (Ref 292) conducted a comprehensive analysis of the valve failure question based on review of the medical literature, prior failure analyses (Ref 293–295), plus their own experiments. They concluded that the risk of failure of such valves is many orders of magnitude greater than would be expected solely from mechanical fatigue. Mechanical fatigue tests (Ref 296) indicate the fatigue life of Haynes 25 exceeds 10^9 heartbeats (30 yr). Xiao and Appleby (Ref 292) concluded the cause of the valve failures is SCC in the less noble weld area, exacerbated by erosion-corrosion. The weld area was seen to be dealloyed and containing residual porosity and carbide inclusions. Given the outstanding SCC resistance of cobalt-base alloys in chloride solutions and the particularly abundant protein concentration in blood plasma, the Björk-Shiley valve experience may be supportive of the hypothesis presented in the prior section that the protein moiety of *in vivo* fluids can make them more aggressive, as far as SCC is concerned, compared to chloride-containing solutions alone.

As a final comment, it should be noted that the number of reports of SCC of retrieved orthopedic implants in the past two decades (1980–2000) has substantially declined, compared to the 20 year period before that. As with CF, this presumably reflects the greater attention that has been paid to improving the chemical composition and metallurgical condition (particularly microcleanliness) of the alloy grades that are acceptable for surgical implants. The lessened frequency of *in vivo* SCC is especially noteworthy for stainless steel implants.

New Materials and Processing Techniques for CF and SCC Prevention

In industrial applications, SCC prevention can be accomplished by modification of the environment, alteration of the metallurgical condition of the material selected for the application, and

changing the loading conditions on the material. For *in vivo* service, however, only the latter two factors remain realistic possibilities.

High-quality surgical implant materials have evolved over the years through the cooperative efforts of biomaterials scientists, manufacturers, surgeons, and regulators. Yet, efforts to improve upon the materials available to orthopedic surgeons continue. For example, pure tantalum (ASTM standard F 560) is a biomaterial that is biocompatible and highly corrosion resistant, as is niobium. Yet, the poor mechanical properties of these materials have restricted their use in load-bearing applications. Pypen et al. (Ref 297) have shown cold work will elevate the endurance limits of these materials compared to the annealed condition by about 10%, which brings the level for tantalum up to that of annealed titanium, which is a material used for dental implants.

New titanium alloys are also under development, as has been mentioned earlier. For example, Niinomi and his coworkers (Ref 298, 299) have performed fatigue tests on a β -titanium alloy Ti-29Nb-13Ta-4.6Zr. He found that, at 10 Hz ($R = 0.1$), the fatigue limit was 700 MPa (102 ksi) when the alloy was given a 1 h solution treatment at 800 °C (1470 °F), and then aged at 400 °C (750 °F) for 72 h to produce fine precipitates (α and ω phases). Okazaki et al. (Ref 300) have also investigated various new titanium alloy formulations. They performed CF testing at 10 Hz in 37 °C (98.6 °F) Eagles medium ($R = 0.1$). They found out that σ_{fs} at 10^8 cycles for annealed Ti-15Zr-4Nb-4Ta and Ti-15Sn-4Nb-4Ta was about 600 MPa (87 ksi). The fatigue strength increased, compared to the annealed condition, when solution treating and aging were performed. For Ti-6Al-2Nb-1Ta, σ_{fs} was 700 MPa (102 ksi) at 10^8 cycles. They also found the σ_{fs} of β -type Ti-15Mo-5Zr-3Al at 10^7 cycles was lower than that of the α/β alloys. In a more recent study, Okazaki (Ref 301) found that for the Ti-15Zr-4Nb-4Ta alloy (β or α/β forged followed by annealing for 2 h at 700 °C, or 1290 °F), a subsequent solution treatment plus aging could increase the σ_{fs} value (using the same test protocol) to 800 MPa (116 ksi). Jablakov et al. (Ref 302) have investigated Ti-35Nb-7Zr-5Ta, a β -titanium alloy that is the most highly alloyed titanium-base biomaterial investigated so far. Because of the high-alloy content, this material has an increased capacity to accommodate interstitial elements without an adverse impact on mechanical properties. When this alloy is cold worked and aged, its endurance limit exceeds that of the Ti-6Al-4V ELI (F 136) and Ti-6Al-4V (F 1472) systems when mill annealed.

Other investigators have studied ways to improve existing titanium-base implant alloys. Filiaggi et al. (Ref 303) applied a ZrO₂ coating on Ti-6Al-4V for the purpose of enhancing implant fixation and showed that the coating did not adversely affect the fatigue strength of the alloy in air (635 MPa, or 92 ksi, at 10^7 cycles). Marquardt (Ref 304) and Nutt et al. (Ref 305)

have described attempts to improve on the fatigue properties of Ti-15Mo (ASTM F 2006) by using innovative thermal treatments that introduce the α phase into the microstructure.

Summary

Much effort has been devoted to the study of CF and SCC of implant alloys, and modifications in composition and processing of biomaterials have been made, so that today's (2006) implants have markedly improved CF and SCC resistance compared to those of only as little as 20 years ago. Yet, because of the uncertainties and variability surrounding the conditions to which implants are actually exposed *in vivo*, and the further difficulty of accurately simulating these in the laboratory, one cannot yet say whether these problems have disappeared and that contemporary implants should be considered to be totally immune to SCC.

Several aspects of these two processes have been clarified and ways have been illuminated so that these failure modes can be minimized under *in vivo* conditions or else point to potentially fruitful avenues of future research into CF and SCC phenomena. First of all, it should be noted that the yield stress is the key element regarding failure of implants. Macroscopic yielding will almost certainly lead to failure of an implant in the functional sense. However, even on the microscopic scale, localized plastic deformation, though sometimes unavoidable, may nevertheless create focal points for initiation of CF and/or SCC, or else potential biocompatibility problems arising from stress-enhanced ion release. Furthermore, the key to preventing CF or SCC is to prevent crack initiation, since the vast majority of the service lifetime of an implant destined to fail by either mechanism is generally spent in the time period when the crack is being initiated.

From the research viewpoint, crack propagation processes are much easier to investigate than is crack initiation. Enhancement of resistance to environmentally assisted cracking, however, will most effectively come about through increased understanding of the factors involved in initiation and exploitation of this understanding for improvement in materials design of implant alloys. There is also a need in SCC and CF research to develop test methods that take into consideration a more realistic simulation of the complex loading modes to which implants can actually be subjected. In addition, chemical environments for SCC and CF testing that more closely simulate *in vivo* conditions in terms of causative agents, particularly organic constituents (especially proteins), should be developed, even though this is a difficult problem to attack.

Though the CF and SCC behavior of certain orthopedic alloys, such as 316L stainless steel and Ti-6Al-4V ELI, has been extensively studied, this is not necessarily true for the newer

alloys for which standards have recently been developed. The SCC and CF resistance of these innovative materials still needs to be assessed in many cases. This is even truer for more experimental materials such as tantalum-, niobium-, and zirconium-base alloy systems. Considering the experience of the Björk-Shiley valve, it is also prudent when older, more traditional implant materials are serving in new applications, stents for example, that their SCC and CF resistance should be thoroughly investigated.

Finally, it again should be pointed out, that over the past 20 years or so (prior to 2006), the orthopedic industry has made substantial improvements in the implant alloys it produces by paying heightened attention to chemical composition, microcleanliness, and optimal processing techniques. This has led to many benefits, including increased CF and SCC resistance. This lesson should be applied to other industries that supply metallic implant devices as well, in particular those that manufacture products for use in the cardiovascular system and for dentistry.

Corrosion and Tarnish of Dental Alloys

Revised by Spiro Megremis, American Dental Association
Clifton M. Carey, American Dental Association Foundation

DENTAL ALLOY DEVICES serve to restore or align lost or misaligned teeth so that normal biting function and aesthetics can prevail. Alloys are used for direct fillings, crowns, inlays, onlays, bridges, fixed and removable partial dentures, full denture bases, implanted support structures, and wires and brackets for the controlled movement of teeth. In addition to applications calling for cast or wrought alloys, other uses of alloys include soldered assemblies, porcelain fused to metal, and resin bonded to metal restorations.

Dental Alloy Compositions and Properties

Dental Alloy Compositions. The compositions of alloys used to fulfill the diverse applications germane to dentistry include the following elements: Au, Pd, Pt, Ag, Cu, Co, Cr, Ni, Fe, Mo, W, Ti, Zn, In, Ir, Rh, Sn, Ga, Ru, Si, Mn, Be, B, Al, V, C, Ta, Zr, and others. Figures 1 to 6 show a number of typical restorations and appliances fabricated from alloys containing some of these metals.

Compositions for direct filling restorations usually consist of silver-tin-copper-zinc amalgams, although this is rapidly changing with the continued improvement of polymer composites. Pure gold in the form of cohesive foil, mat, or powder is used only in very limited applications.

Alloys for all-alloy cast crown and bridge restorations are usually gold-, silver-, or nickel-base compositions, although iron-base and other alloys have also been used. The gold-base alloys contain silver and copper as principal alloying elements, with smaller additions of palladium, platinum, zinc, indium, and other noble metals as grain refiners. The silver-base alloys contain palladium as a major alloying element, with additions of copper, gold, zinc, indium, and grain refiners. The nickel-base alloys are alloyed with chromium, iron, molybdenum, and other elements.

Alloys for porcelain fused to alloy restorations are gold-, palladium-, nickel-, or cobalt-base compositions. The gold-base alloys are divided into gold-platinum-palladium, gold-palladium-silver, and gold-palladium types. The palladium-base alloys are palladium-silver alloys or palladium-gallium alloys with additions from either copper or cobalt. The nickel- and cobalt-base alloys are alloyed primarily with chromium and with minor additions of molybdenum and other elements. In contrast to alloys for crown and bridge use, alloys fused to porcelain contain low concentrations of oxidizable elements, such as tin; indium; iron; gallium for the noble metal containing alloys; and aluminum, vanadium, and others for the base metal alloys. During the heating cycle, these elements form oxides on the surface of the alloy and combine with the porcelain at the firing temperatures to promote chemical bonding.

Alloys for removable partial dentures are primarily nickel- and cobalt-base compositions and are similar to alloys used for porcelain fused to alloy applications. However, carbon is present in amounts up to 0.3 to 0.4% with the partial denture alloys. Carbon is not added to alloys to be used for porcelain bonding.

Alloys that have found applications for support structures implanted in the lower or upper jaws are composed of cobalt-chromium, nickel-chromium, stainless steel, and titanium and its alloys. Wrought orthodontic wires are composed of stainless steel, cobalt-chromium-nickel, nickel-titanium, and β -titanium alloys. Silver- and gold-alloy solders are used for the joining of components. High-temperature brazing alloys are used for the joining of a number of high fusing temperature alloys. Additional information on noble metals is available in the article "Corrosion of Precious Metals and Alloys" in *Corrosion*, Vol 13B, of the *ASM Handbook*.

Properties. The diversity in available alloys exists so that alloys with specific properties can be used when needed. For example, the mechanical property requirements of alloys used for crown and bridge applications are different from the requirements of alloys used for porcelain fused to alloy restorations. Even though crown and bridge alloys must possess sufficient hardness and rigidity when used in stress-bearing restorations, excessively high strength is a disadvantage for grinding, polishing, and burnishing. Also, excessive wear of the occluding teeth

Fig. 1 Various types of crowns. Source: Ref 1

Fig. 2 Various types of inlays. Source: Ref 1

is also likely to occur. Alloys used with porcelain fused to metal restorations are used as substrates for the overlaying porcelain. In this case, the high strength and rigidity of the alloys more closely matches the properties of the porcelain. Also, a higher sag resistance of the alloy at temperatures used for firing the porcelain means less distortion and less retained residual stresses.

Similarly, alloys used for partial denture and implant applications must possess increased mechanical properties for resistances to failures. However, clasps contained within removable partial denture devices are often fabricated from a more ductile alloy, such as a gold-base alloy, than from cobalt-chromium or nickel-chromium alloys. This ensures that the clasps possess

sufficient ductility for adjustments without breakage from brittle fractures.

Other properties required in specific systems include the matching of the thermal expansion coefficients between porcelain and substrate alloy, negligible setting contractions with the direct filling amalgams, and specific modulus to yield strength ratios with orthodontic wires. Tarnish and corrosion of all dental alloy systems have been and will remain of prime importance.

Tarnish and Corrosion Resistance

Dental alloy devices must possess acceptable corrosion resistance primarily because of safety and efficacy. Aesthetics is also a consideration.

Safety

Dental alloys are required to have acceptable corrosion resistance so that biocompatibility is maintained during the time the metallic components are used (Ref 5–7). No harmful ions or corrosion products can be generated such that toxicological conditions result. The effects of the dental alloys on the oral environment have the capabilities for producing local, remote, or systematic changes that may be short term, long term, or repetitive (tissue sensitization) in nature

(Ref 8). Dental alloy-oral environment interactions have the potential for generating such conditions as metallic taste, discoloration of teeth, galvanic pain, oral lesions, cariogenesis, allergic hypersensitive reactions, dermatitis and stomatitis, endodontic failures, dental implant rejection, tumorigenesis, and carcinogenesis. Figure 7 shows a schematic of useful dental anatomy.

Metallic Taste. The symptom of metallic taste has been reported and related to the presence of metallic materials in the mouth (Ref 9). In addition, the release of ions and the formation of products through corrosion, wear, and abrasion can occur simultaneously, which can accelerate the process. Therefore, patients with metallic restorations and with an inclination toward bruxism (the unconscious gritting or grinding of the teeth) are likely to be more susceptible to metallic taste. Although this condition is not as prevalent as it once was when metallic materials with lower corrosion resistances were more often used, metallic taste is still known to occur on occasion.

Discoloration of teeth has occurred mainly with amalgam fillings (Ref 10) and with base alloy screwposts (Ref 11). With amalgams, tin and zinc concentrations have been identified in the dentinal tubules of the discolored areas, while with the screwposts, copper and zinc were

detached in both the dentin and enamel and the surrounding soft connective tissue. Discoloration is not, however, a definite indicator of the presence of metallic ions.

Galvanic pain has been reported from the contact of dissimilar-alloy restorations, either continuously or intermittently (Ref 9, 12). An electrochemical circuit occurring between the two dissimilar-alloy restorations is short circuited by the contact. In the case of intermittent contact, instantaneous current flows through the external circuit, which is the oral tissues, and may cause pain. The placement of dissimilar-alloy restorations in direct contact is ill advised.

Oral lesions resulting from the metallic prosthesis contacting tissue can be due to physical factors alone (Ref 9). An irritation in the opposing tissues of the oral mucosa can be generated because of the shape and location in the mouth of the prosthesis, as well as its metallurgical properties, such as surface finish, grain size, and microstructural features. Tarnish and

corrosion can change the nature of the alloy surface and add to the irritation in the opposing tissues. Microgalvanic currents due to chemical differences of microstructural constituents must also be considered as possible causative factors in traumatizing and damaging tissue. However, no data have related *in vivo* galvanic currents from dental restorations to tissue damage. The released metallic ions from corrosion reactions can interact with the oral tissues to generate redness, swelling, and infection. Oral lesions can then occur. These reactions are discussed in the section "Allergic Hypersensitive Reactions" in this article.

Cariogenesis corresponds to the ability for released metallic ions and formed corrosion products to affect the resistance of either dentin or enamel to decay (caries). The mechanisms involved with caries formation (Ref 13–15), which include the fermentation of carbohydrate by microorganisms and the production of acid, are likely to become altered when metallic ions and products from corrosion reactions are included. This may be indicated by the reports that show tin and zinc concentrations (originating from amalgam corrosion) in softened, demineralized dentin and enamel (Ref 16–18).

Allergic Hypersensitive Reactions. With allergic hypersensitive contact reactions, some people can become sensitized to particular foreign substances, such as ions or products from the corrosion of dental alloys (Ref 9, 19). The metallic ions or products combine with proteins in the skin or mucosa to form complete antigens. Upon first exposure to the foreign substance by the oral mucosa, sensitization of the host may occur in times of up to several weeks and with no adverse reactions. Thereafter, any new exposures to the foreign substance will lead to biological reactions, such as swelling, redness, burning sensation, vesiculation, ulceration, and necrosis. Abstinence from the foreign substance leads to healing. Identification and avoidance are the means for controlling these allergic hypersensitive reactions. Exposure of the oral mucosa to the foreign substance can lead not only to allergic stomatitis reactions (of the oral mucosa), but also to allergic dermatitis reactions (of the skin) at sites well away from the contact site with the oral mucosa. However, because the oral mucosa is more resistant to allergic reactions than the skin, the reverse process usually does not occur.

Of the currently used metals contained in dental alloys, nickel, cobalt, chromium, mercury, beryllium, and cadmium need to be considered as inducing possible allergic or cytotoxic reactions. Nickel is the primary alloying element in nickel-chromium casting alloys (up to 80%), in nickel-titanium wires (up to 50%) and in lower concentrations in some cobalt-chromium alloys, and in austenitic stainless steels. Nickel from dental alloy is known to react with the oral tissues in some individuals to produce allergic sensitization reactions (Ref 20). About 9% of women and 1% of men are estimated to be allergic to nickel. It is recommended

that individuals be screened for possible nickel allergies prior to dental treatments. If an allergy arises from a nickel-containing dental restoration, it is recommended that the individual be tested for allergies to nickel and, if so indicated by the test results, have the restoration replaced with a nickel-free alloy.

Cobalt, also a component of some dental alloys, has been known to react with the oral mucosa and cause allergic reactions (Ref 20). However, the occurrences of such allergies are less than 1% of the population and mainly affect women. If reactions to cobalt from cobalt-containing materials are suspected, then testing for cobalt allergies should be performed. Contact allergic reactions to chromium from dental alloys are also reported (Ref 20), but the occurrences of such reactions are rare.

Mercury is contained in amalgam fillings, which contain microstructural phases composed of silver-mercury and tin-mercury. Mercury ions may be released from microstructural phases through corrosion. However, the concentrations are low and not relatable to toxicological ramifications. Mercury vapors released from amalgam surfaces may also occur. Again, because of the low concentrations emitted, amalgam mercury vapors are not related to toxicity. Allergic reactions to mercury contained in dental amalgams have been reported (Ref 20). If mercury allergic reactions are suspected from the amalgam, it is recommended that testing for mercury allergies be conducted.

Beryllium is contained in some nickel-chromium casting alloys in concentrations up to about 2 wt%. There are only a few cases of transient contact dermatitis that have been reported among dental professionals (Ref 21, 22). More of a health hazard is posed to the dental personnel doing the actual melting and finishing of the alloy than to individuals having a prosthesis made from a beryllium-containing alloy. For instance, the Occupational Safety and Health Administration (OSHA) has posted a Hazard Information Bulletin titled "Preventing Adverse Health Effects from Exposure to Beryllium in Dental Laboratories" expressing its concern about reports of chronic beryllium disease among dental laboratory technicians that are exposed to dust from melting, grinding, polishing, and finishing beryllium-containing alloys (Ref 23). As a result of safety concerns about beryllium, the American Dental Association (ADA) Council on Scientific Affairs recommends that dentists "use alloys that do not contain beryllium in the fabrication of dental prostheses" (Ref 24). Furthermore, the European Committee for Standardisation passed a resolution in February 2002 recommending that all standards pertaining to dental alloys permit a maximum beryllium content of only 0.02% wt%, which essentially excludes its use as an alloying element (Ref 25).

Cadmium is contained in some dental gold and silver solders of up to 15% (Ref 26). No biological reactions have been related to the cadmium contained in these materials; however,

precautions should be taken in fusing solders containing cadmium.

Additional information on the biocompatibility of metals and acceptable exposure limits is available in the article "Toxicity of Metals" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Vol 2, of the *ASM Handbook* (refer to pages 1233 to 1269).

Endodontic Failures. Root canals obturated with silver cones (or points) have occasionally been associated with corrosion (Ref 27). Figure 8 shows examples of restored teeth including two cases of endodontically treated teeth. Development of a fluid-tight seal at the apex of the root canal is the primary objective of endodontic therapy. Corrosion of the silver points is known to lead to failure by allowing the penetration of fluids along the silver cone/root canal interface. Figure 8(b) shows a schematic of a tooth with cones.

Dental Implant Rejection. Dental implants, which are used for permanently attaching bridges, and so on, extend through or up to the maxillary or mandibular bones and must function in both hard and soft tissues, as well as within a wide range of applied stresses (Ref 28, 29). Depending on the chemical inertness of the materials used for these devices, the thickness of the tissue connecting implant to bone varies. Released ions can infiltrate thick membranes surrounding loosely held implants, which can lead to an early rejection of the implant through immune response.

Tumorigenesis and Carcinogenesis. Even though dental alloy devices have not been implicated with tumorigenesis and carcinogenesis, their possible formation must never be ruled

out and should always be considered as potential biological reactions, especially with new, untried alloys (Ref 29).

Efficacy

The oral environment must not induce changes in physical, mechanical, chemical, optical, and other properties of the dental alloy, such that inferior functioning and/or aesthetics result. The effect of the oral environment on the alloy has the potential for altering dimensions, weight, stress versus strain behavior, bonding strengths with other alloys and with nonmetals, appearances, and creating or enhancing crevices. In combination with mechanical forces, the oral environment is capable of generating premature failure through stress corrosion and corrosion fatigue and of generating increased surface deterioration by fretting, abrasion, and wear.

Dimensions, Weight, Mechanical Properties, and Crevices. At least in theory, corrosion of precision castings and attachments, which rely on accurate and close tolerance for proper fit and functioning, can alter their dimensions, thus changing the fit and functionality of the restorations. Similarly, corrosion of margins on crowns and other cast restorations can lead to decreased dimensions and to enhanced crevice conditions. The increased seepage of oral secretions into the crevices created between restoration and tooth can lead to microorganism invasion, generation of acidic conditions, and the operation of differential aeration cells. Under these conditions, the bonding of the restoration to the dentinal walls through the underlying

cement is likely to become weakened. In combination with biting stresses, microcrack formation along the interface is likely to occur; this will cause the penetration of the crevice even further beneath the restoration. Eventually, the loosening of the entire restoration may occur.

With amalgam restorations, however, a slight amount of corrosion on these surfaces adjacent to the cavity walls may actually be beneficial because corrosion product buildup increases dimensions and adaptability. The crevice between an amalgam and the cavity is reduced in width, which leads to a decreased seepage of fluids. Additionally, the corrosion surface may inhibit bacterial growth, thus reducing bacterial invasion of small crevices. On the other hand, corrosion of the amalgam deteriorates its sub-surface structure; this is likely to lead to an increased occurrence of marginal fracture, a known problem with amalgams, through corrosion fatigue mechanisms with stresses generated from biting (Ref 30).

The loss of sufficient material from any dental alloy through corrosion can lead to a reduction in mechanical strength. This can lead to a direct failure of the alloy or reduced rigidity resulting in unacceptable strains. For silver-soldered wires, corrosion of the solder leads to a weakening of the entire joint (Ref 31). Loosening of crowns and bridges because of corrosion-induced fractures of posts and pins is also known to occur (Ref 32), as shown in Fig. 8(a) and (c). Still other possibilities of the effects of corrosion include the reduction in bond strengths of metal brackets bonded to teeth, as well as the degradation of porcelain fused to metal restorations.

Appearance. Because of the various optical properties of corrosion products, the appearance of tarnished and corroded surfaces can become unacceptable. A degradation in surface appearance, without a loss in the properties of the appliance, can be taken to be either acceptable or unacceptable, depending on individual preferences. If, however, the tarnished surface promotes additional consequences, such as the attachment of plaque and bacteria or a greater irritation to opposing tissue, then tarnishing must be deemed unacceptable.

Interstitial versus Oral Fluid Environments and Artificial Solutions

In order to select and/or develop dental alloys, an understanding of the environment to which these materials will be exposed is imperative. This section defines and compares interstitial fluid and oral fluid environments. In addition, artificial solutions developed for testing and evaluation of dental materials also are discussed.

Interstitial Fluid

Applications of metallic materials to oral rehabilitation are confronted with a number of

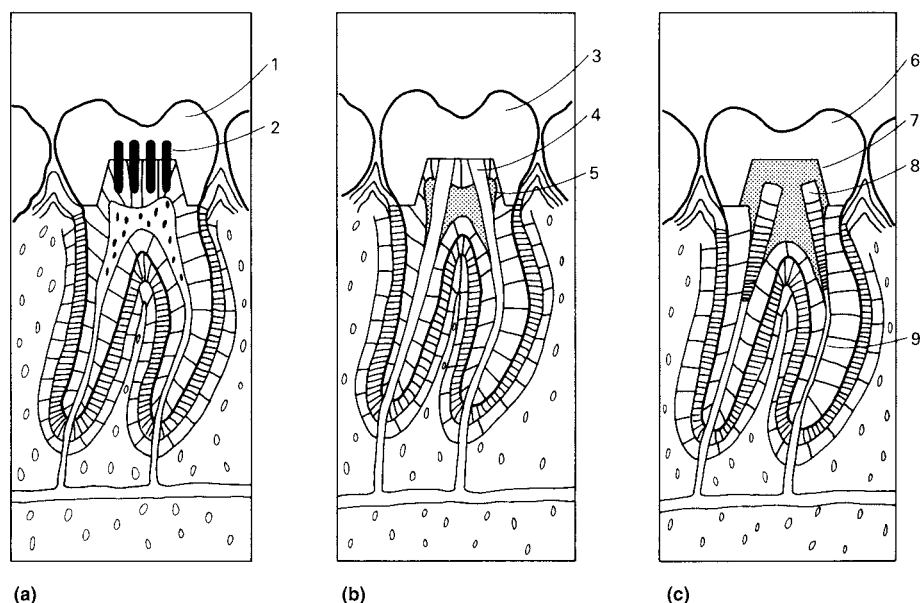

Fig. 8 Typical restored teeth. (a) Pin restored amalgam filling on vital tooth. (b) Cast metal crown restoration on endodontically treated tooth with silver cones and cement to seal root canals. (c) Cast metal crown restoration on endodontically treated tooth with cement core buildup and screwposts. 1, amalgam filling; 2, stainless steel pins; 3, metal crown; 4, silver cones; 5, cement; 6, metal crown; 7, cement core; 8, screw posts; 9, gutta-percha or similar sealing material

environmental conditions that differentiate most dental uses from other biomedical uses (Ref 33). The one major exception is dental implants because interstitial fluids (the fluids in direct contact with tissue cells) are encountered by both dental and other types of surgical implants (see, for example, the article "Corrosion Effects on the Biocompatibility of Metallic Materials and Implants" in this Volume). As discussed later in this article, other exceptions occur because restorations in teeth have their interior surfaces in direct contact with the dentinal and bone fluids, which are more similar to interstitial fluids in composition than to saliva.

Other types of extracellular fluids, such as lymph and blood plasma, contain similar inorganic contents and are also likely to come into contact with dental implants, particularly with plasma during and shortly after surgery. Table 1 presents a composition of blood plasma. The inorganic content is similar to the inorganic content of interstitial and other types of extracellular fluids, while the protein concentration for plasma is higher than for other biofluids. For plasma, the major proteins are albumin, globulins, and fibrinogen. For all extracellular fluids, the inorganic contents are characterized by high sodium (Na) and chloride (Cl^-) and moderate bicarbonate (HCO_3^-) contents. Considerable variations in pH, p_{O_2} , and p_{CO_2} can occur in the vicinity of an implant. In crevices formed between plates and screws, some extreme values ranging between 5 to 7 in pH,

and <8 to 110 and <10 to 300 mm Hg, respectively, have been determined (Ref 35). Similar corrosive conditions are expected regardless of the extracellular fluid, provided the effects of the protein and cellular contents are minimal.

Tissue cells and other types of cellular matter can also directly contact implant material, with the possibility of intracellular fluid permeating through the cell membrane and effecting corrosion of the alloy. Separation by shearing of biological cells from alloy surfaces almost always generates cohesive failures through the cell instead of adhesive failures along the alloy/cell interface (Ref 36). In these situations, intracellular fluids can gain direct access to the surface of the alloy. In contrast to extracellular fluids, intracellular fluids contain high potassium and organic anion contents. The sodium is replaced by potassium and Cl^- by orthophosphate (HPO_4^{2-}). The effectiveness of intracellular fluids in corroding implant surfaces will be governed by the ability of the larger organic anions to pass through cell membranes, which are usually very restricted. Extracellular fluids are, therefore, the fluids interacting with the implant in most cases, although the possible effects from intracellular fluids must not be dismissed.

Oral Fluids

Whole mixed saliva is produced by the paratid, submandibular, and sublingual glands, together with the minor accessory glands of the cheeks, lips, tongue, and hard and soft palates

from the oral mucosa. Gingival or crevicular fluid is also produced, as well as fluid transport between the hard tissues of the teeth and saliva. The composition of the secretion from each gland is different and varies with flow rate and with the intensity and duration of the stimulus. Saliva composition varies from individual to individual and in the same individual under different circumstances, such as time of day and emotional state.

Although about 1 L of saliva is produced per day in response to stimulation accompanying chewing and eating, for the greater part of the day, the flow rate is at very low levels (0.25 to 0.5 mL/min) (Ref 37, 38). During sleep, there is virtually no flow from the major glands. At low flow rates, the concentrations of sodium, Cl^- , and HCO_3^- are reduced notably; the concentration of calcium is elevated slightly; and the concentrations of magnesium, phosphate (PO_4^{3-}), and urea are elevated decidedly when compared with stimulated flow rates (Ref 39). It is therefore impossible to define specific compositions and concentrations that are universally applicable. However, compilations of data encompassing large statistical populations have been made by a number of researchers. One typical analysis for the composition of human saliva is shown in Table 2.

The inorganic ions readily detectable in saliva are Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , PO_4^{3-} , HCO_3^- , thiocyanate (SCN^-), and sulfate (SO_4^{2-}). Minute traces of F^- , I^- , Br^- , Fe^{2+} , Sn^{2+} , and nitrite (NO_2^-) are also found, and on occasion, Zn^{2+} , Pb^{2+} , Cu^{2+} , and Cr^{3+} are found in trace quantities. Figure 9 shows the Cl^- and HCO_3^- variations in concentration as saliva is stimulated to a flow rate of 1.5 mL/min. The O_2 and N_2 contents of saliva are 0.18 to 0.25 and 0.9 vol%, respectively. The carbon dioxide (CO_2) content varies greatly with flow rate, being about 20 vol% when unstimulated and up to about 150 vol% when vigorously

stimulated. The buffering capacity is chiefly due to the $\text{CO}_2/\text{HCO}_3^-$ system, with that of the PO_4^{3-} system only having a small, limited part. The redox potential of saliva indicates it to possess reducing properties, which is likely due to bacteria reductions, carbohydrate splitoffs from glycoproteins, and nitrates. The normal pH of unstimulated saliva is in the 6 to 7 range and increases with flow rate.

The clearance of saliva involves its movement toward the back of the mouth and its eventual introduction into the stomach. Saliva is continually being secreted and replenished, especially during active times. A volume of about 1 L/d is considered average for saliva production. Chemical analysis of human mouth air showed hydrogen sulfide (H_2S), methyl mercaptan, and dimethyl sulfide to be some of the most important constituents (Ref 39).

Organic. Human saliva is composed of non-protein organic and protein contents, as shown in Table 2. The largest contributions from the nonprotein ingredients are from the carbohydrates, while smaller amounts are from urea, organic acids, amino acids, ammonia, sugars, lipids, blood group substances, water-soluble vitamins, and others. Some of the lipids include the fatty acids, glycerides, and cholesterol. At least 18 amino acids have been identified, with glycine being the main constituent. Many of these components are produced directly by the salivary glands, while others, such as some carbohydrates and amino acids, are the result of the dissociation of glycoproteins and proteins by bacterial enzymes. Still others are derived from blood plasma. The protein content of human saliva is primarily of salivary gland origin, with a very small amount derived from blood plasma. The protein content may vary from less than 1 to more than 6 g/L. Detailed information on protein and glycoproteins that have been identified to be in saliva can be found in Ref 40 to 42.

Chemicals in Food, Drink, and Air. All of the ingredients found in food and drink are capable of becoming incorporated into saliva. However, most of the foods are ingested before the breakdown into basic chemicals occurs. Some foods and beverages, though, contain chemicals that are reactive by themselves, without any reductions, and may become dissolved in saliva and affect the tarnish and corrosion of metallic materials. Some of these include various organic acids, such as lactic, tartaric, oleic, ascorbic, fumaric, maleic, and succinic, as well as sulfates, chlorides, nitrates, sulfides, acetates, bichromates, formaldehyde, sulfoxylates, urea, and the nutrients themselves of lipids, carbohydrates, proteins, vitamins, and minerals (Ref 43).

The components found in atmospheric air and pollutants, coupled with the human respiratory function, have the potential of exposing the oral environment to additional aggressive chemical species. Some of the species known to be in atmospheric air and pollutants are O_2 , CO_2 , NO_2 , carbon monoxide (CO), sulfur dioxide (SO_2), Cl_2 , hydrogen chloride (HCl), hydrogen sulfide (H_2S), ammonia (NH_3), formaldehyde, formic

acid, acetic acid, Cl^- salts, ammonium salts of sulfate and nitrate, and dust (Ref 44).

Because the volume of lung ventilation is of the order of 8.5 L/min, the amount of potentially hazardous and corrosive material possibly coming into contact with the oral environment is significant. In approximately 2 h, 1 m^3 of air (for a mouth breather) will have been used during respiration, with the potential uptake of sulfur dioxide in the normal urban area being 0.11 to 2.3 mg. Sulfur dioxide can be involved in many interactions, accelerating the tarnish and corrosion of metals. Fortunately, the proteins in saliva combine with most of the aggressive external stimuli coming into contact with saliva; therefore, most of the aforementioned hazardous species are rendered inactive before they can cause tarnish and corrosion. However, the pathway from the atmosphere to the surfaces of dental alloys are certainly potential sources for introducing corrosive species.

A comparison between interstitial and oral fluids shows differences in both inorganic and organic contents. One important difference is the approximately sevenfold higher Cl^- concentration in interstitial fluid. Even though interstitial fluids do undergo variations in pH and $p\text{O}_2$, especially at the site of the implant, saliva is more susceptible to variations in composition. This comes about because the composition of saliva depends to a large degree on flow rate, which in turn depends on a number of physical and emotional factors. Saliva is also subjected to exposures from chemicals contained in the air, food, drink, pharmaceuticals, as well as temperature variations of 0 to 60 °C (32 to 140 °F) and microbiological involvement with the production of acid and plaque.

Artificial Solutions. Numerous solutions simulating human saliva have been formulated and used for testing the tarnish and corrosion susceptibility of dental alloys (Ref 45–50). Modifications to these solutions have also been made and used (Ref 51–56). Some of the solutions contain only inorganics (Ref 48–50, Ref 52–54), while others include the addition of an organic component consisting mostly of mucin (Ref 45–47, 51–53). Some researchers also purge a $\text{CO}_2/\text{O}_2/\text{N}_2$ gas mixture through the solution to simulate pH control and buffering capacity controlled by the $\text{CO}_2/\text{HCO}_3^-$ redox reaction. All compositions contain mostly chlorides (Na, K, and Ca) and various forms (mono-, di-, or tri-basic, pyro) of phosphates in smaller amounts. Additional ingredients include bicarbonate, thiocyanate, sulfide, carbonate, organic acids, citrate, hydroxide, and urea.

Table 3 presents the composition for an artificial saliva that corresponds very well to human saliva, with regard to the anodic polarization of dental alloys. Ringer's physiological saline solution used to simulate interstitial fluid is also included in Table 3. Both solutions are entirely inorganic. The Cl^- concentration of Ringer's is about seven times higher than that of the saliva. The anionic content of Ringer's is entirely chloride, while the artificial saliva also contains

phosphate and sulfide. Urea is also a constituent of the artificial saliva. Sodium, potassium, and calcium constitute the cationic content of both solutions.

A number of additional artificial physiological solutions, some of which are named Hanks, Tyrod, Locke, and Krebs, appear in the literature and have been used to simulate the interstitial fluids. Basically, these solutions contain small additions of modifying ingredients, such as magnesium chloride, glucose, lactate, amino acids, and organic anions. The Ringer's solution presented in this article, after the National Formulary Designation, does not contain sodium bicarbonate (NaHCO_3^-). Some solutions, however, referred to in the literature as Ringer's, do contain bicarbonate.

Effect of Saliva Composition on Alloy Tarnish and Corrosion

Chloride/Orthophosphate/Bicarbonate/Thiocyanate. The interactions of the various salts contained in saliva are complex. The effects from the combined saliva solutions are not simply the additive effects from the isolated individual salts. This synergistic behavior is discussed for the corrosion of an amalgam in the $\text{Cl}^-/\text{HPO}_4^{2-}/\text{HCO}_3^-/\text{SCN}^-$ system in Ref 50. Chloride alone produces a powdery, finely crystalline corrosion product in heaps around the sites of attack, such as porosities and pits. The addition of HPO_4^{2-} , which by itself produced very little effect, caused the corrosion products to become organized in conical structures, the bases being over the sites of corrosion. The addition of HCO_3^- to the $\text{Cl}^-/\text{HPO}_4^{2-}$ system generated increased microstructural corrosion. On the contrary, addition of SCN^- to the $\text{Cl}^-/\text{HPO}_4^{2-}$ system suppressed the microstructural corrosion. By adding all four salts together, an even more corrosion-resistant system was obtained. Corrosion was much reduced and more localized.

Artificial Salivas. The effect on alloy corrosion from different artificial saliva solutions has been studied (Ref 49). The polarization behavior of a number of dental alloys, including gold-base alloys, nickel-chromium, and cobalt-chromium, in artificial salivas without HCO_3^- and SCN^- , but with protein, provided the best correlation with the behavior observed with human saliva in both aerated and deaerated conditions. The

Table 3 Composition of artificial solutions

Source: Ref 49

artificial salivas containing HCO_3^- and SCN^- , but no proteins, constantly shortened the passivation range of the alloys. The specific contributions from Cl^- and SCN^- shortened the passivation range of the gold-base alloy, but phosphate increased the passivation range of all alloys.

Lowering the pH shifted the amalgam polarization curve to increased currents and potentials, while buffering capacity, which was increased by protein content, influenced corrosion behavior under localized corrosion conditions (Ref 57). In sulfide solution, the polarization curves of amalgams indicated increased corrosion (Ref 47, 58). Dissolved O_2 generated both inhibition and acceleration, as reflected by the formation of anodic films and the consumption of electrons by cathodic depolarization. The particular alloy-environment combination determines whether corrosion is inhibited or accelerated.

Chloride and Organic Content. Anodic polarization of amalgams in human saliva compared with Ringer's solution was shown to be shifted by up to several orders of magnitude to lower currents at constant potentials, depending on the amalgam system (Ref 59). These differences were related to the Cl^- concentration of the solutions. The effect of Cl^- on amalgam polarization is well documented (Ref 55, 60, 61). Pretreatment of gold-base alloys in human saliva prior to galvanic coupling with amalgams in a protein-free artificial saliva reduced the corrosion on some of the amalgams studied (Ref 62). Pretreatment of the amalgams had little effect.

Significant reductions in the weight gains of amalgams stored in artificial saliva with mucin as compared with mucin-free saliva have been reported (Ref 47). Anodic polarization of amalgams in artificial saliva or diluted Ringer's solution, with and without additions of mucin or albumin, was, however, shown to be very similar (Ref 47, 60). Proteins in artificial saliva on silver-palladium and nickel-chromium alloy polarizations were also reported to have little effect (Ref 57). For a copper-aluminum crown and bridge alloy, anodic polarization differences were detected in an artificial saliva with and without additions of a human salivary dialysate (Ref 63). The total accumulated anodic charge passed from corrosion potentials to +0.3 V versus saturated calomel electrode (SCE) was significantly reduced in protein-containing saliva. Similarly, the polarization resistance of the alloy was more than doubled by progressively adding up to 1.6 mg dialysate/mL to saliva initially free of proteins.

Microorganisms. The tarnishing of dental alloys by three microorganisms likely to be found in the mouth has been reported (Ref 64). Some specificity between the degree of tarnish and the type of microorganism was obtained. A likely tarnishing mechanism was due to the organic acids generated by the fermentation of carbohydrate by the bacteria. The effect of microorganisms on accelerating corrosion is

discussed in the section "Oral Corrosion Processes" in this article.

Oral Corrosion Pathways and Electrochemical Properties

The electrochemical properties of dental alloy restorations vary widely. Electrochemical potentials, current pathways, and resistances depend on whether there is no contact, intermittent contact, or continuous contact between alloy restorations. This section examines the effects of restoration contact on electrochemical parameters and reviews concentration cells developed by dental alloy-environment electrochemical reactions.

Noncontacting Alloy Restorations

Isolated. The total liquid environment of a restoration includes, in addition to saliva, fluids contained within the interior of dentin and enamel, which are more like extracellular fluids in composition than saliva. Figure 10 shows a schematic of a likely current path for a single metallic restoration. The current path encompasses a route that includes the restoration, enamel, dentin, membranes such as the periodontal ligament, soft tissues, and saliva (see Fig. 7). The conduction of current through hard tissues, including enamel, dentin, and bone, occurs through the extracellular fluids, which are compositionally similar in all hard and soft tissues. However, the current through these different hard tissues will take pathways of least resistances. For example, the resistance of

dentin in a direction parallel to the tubules is about 18 times lower than in a perpendicular direction due to the calcification of the tubule walls. Structural details, including imperfections, orientations, and so on, control the actual resistances for particular hard tissue structures.

The restoration (R) develops electrochemical potentials with the extracellular fluids, E_{RE} , and with saliva E_{RS} , while a liquid junction potential occurs between extracellular fluids and saliva, E_{ES} . Contact resistances occur between restoration and extracellular fluids, R_{RE} , and between restoration and saliva, R_{RS} . In general, these potentials generated at interfaces are caused by the materials and/or liquids existing at different energy levels. Resistances of the extracellular fluids, R_E , extracellular fluid-saliva junction, R_{ES} , and of saliva, R_S , also occur. Figure 11 shows an electrical schematic for this system. Summing electromotive forces in one direction and equating to zero yields for the current I :

$$I = \frac{E_{RE} + E_{ES} - E_{RS}}{R_{RE} + R_{RS} + R_E + R_S + R_{ES}} \quad (\text{Eq 1})$$

Taken together, E_{ES} and R_S have negligible effect on current. The extracellular resistance, R_E , is usually in the range between 10^4 and $10^6 \Omega$ because of variations in particular hard tissue structures, and to possible variations in membrane/hard tissue interfacial characteristics. The potentials E_{RE} and E_{RS} are characteristics of the metal-electrolyte combinations, and the resistances R_{RE} and R_{RS} are dependent on the polarization characteristics for the particular combinations.

Polarization is related to the corrosion products that form. For soluble or loosely adhered products, the contact resistances will not be changed significantly. However, for tenaciously adhering products with semiconducting or insulating electrical characteristics, the contact resistances will be largely affected. These resistances are the primary parameters affecting the magnitude of the generated current. This reasoning is directly in line with the mixed-potential theory for electrochemical corrosion (Ref 65). The corrosion current, I_{corr} , without ohmic resistance control is:

$$I_{\text{corr}} = \frac{\beta_a \beta_c}{(\beta_a + \beta_c) R_p} \quad (\text{Eq 2})$$

Fig. 10 Schematic of a single metallic restoration (R) showing two possible current (I) paths between external surface exposed to saliva and interior surface exposed to dentinal fluids. Because the dentinal fluids contain a higher Cl^- concentration than saliva, it is assumed the electrode potential of interior surface exposed to dentinal fluids is more active and is therefore given a negative sign ($-$). The potential difference between the two surfaces is represented by E .

Fig. 11 Electrical schematic representing the equivalent circuit of a single loop shown in Fig. 10. Terms are defined in text.

where β_a and β_c are the Tafel slopes from the anodic and cathodic polarization curves, and R_p is the polarization resistance or the linear slope of the $\Delta E/\Delta I$ curve within ± 10 mV of the corrosion potential.

Nonisolated. For two restorations not in contact (Fig. 12), the extracellular fluid-saliva resistance, R_{ES} , determines the extent to which the current will be short circuited through the saliva/extracellular fluid interface. If R_{ES} is high, there is maximum interaction between the separated restorations (the currents are small, of the order of 1 to 10×10^{-9} A/cm² between an amalgam and a gold alloy restoration). As R_{ES} decreases, the current through the interface between saliva and extracellular fluids increases. The interaction between the separated restorations will then be minimized. Each restoration, though, will still generate its own current path loop (Ref 66).

Intraoral Electrochemical Properties. In a study comprising 115 people, the corrosion potentials from 243 restorations ranged between -0.55 and $+0.4$ V versus SCE. Amalgam restorations were the most active, followed by cobalt-chromium alloys and gold-base alloys. Variations in potential on different surfaces of the same restoration occurred routinely. This was likely due to the effects from abrasion on the occlusal surfaces and from the accumulation of plaque and debris on nonocclusal surfaces (Ref 67).

For noncontacting amalgam and gold alloy restorations (78 fillings in 66 people), the average currents flowing through the restorations due to saliva-bone fluid liquid junction cells were calculated from measured intraoral potential and resistance data to be 0.48 and 0.26 μ A, respectively (Ref 12).

Using constant current pulses (1 to 10 μ A) and measuring the corresponding potential changes, the intraoral polarization resistances

for noncontacting amalgam restorations ranged between 50 and $300 \times 10^3 \Omega$ (Ref 68). With the use of linear polarization theory, corrosion currents are calculated to be 0.2 to 1.0 μ A.

Restorations Making Intermittent or Continuous Contact

Intermittent Contact. A situation can occur in the mouth in which two alloy restorations, one in the upper arch and the other in the lower arch, come into contact intermittently by biting (Fig. 13). When the two restorations are in direct contact, a galvanic cell is generated with an associated galvanic current short-circuited between the two restorations. The external current path can take a number of directions, with the least resistance path controlling. Figure 13 shows two possible pathways, one entirely through extracellular fluids and the other partly through extracellular fluids and partly through saliva.

The current-time transients have been measured and are presented in Fig. 14. Upon first making contact, currents of the order of 10 μ A and more occur and decrease rapidly within a matter of minutes. If, however, the restorations are open-circuited for a time interval and then

again closed, the current level will again increase but not to the same magnitude as from the previous closure. The amount of recovery will increase as the time lapse between closure increases. This phenomenon is explained by the formation of protective surface films on the electrodes due to the passage of current. Upon making contact on succeeding occasions, the film offers additional resistance to the flow of current, even though the two restorations appear to be in direct intimate contact. The films dissipate with time, thus increasing the level of the initial current on recontacting restorations.

A similar situation can occur because of an alloy restoration contacting, for example, eating utensils or dental instruments during dental treatment. Again a short-circuited galvanic current is generated. The external circuit will be partly through saliva and partly through extracellular fluids.

Continuous Contact. Another situation in which metallic restorations in the mouth are capable of generating galvanic currents involves two dissimilar metallic restorations in continuous contact, as shown in Fig. 15. Most attention has been given to the combination of amalgam-gold alloy couples (Ref 52). Other situations

Fig. 12 Schematic of two nonisolated, noncontacting restorations. The alloy restoration on the left, which is an amalgam, is more active than the restoration on right, which is a gold-base alloy.

Fig. 13 Schematic of two restorations making intermittent contact due to biting. The restoration in the lower arch, which is an amalgam, is more active than the restoration in the upper arch, which is a gold-base alloy. Two possible current pathways are shown. An additional path very likely to occur would be directly through saliva between the two restorations.

Fig. 14 Current-time responses between gold alloy and amalgam of the same cross-sectional areas. Short circuiting occurred for 15 s, followed by a 2 min delay before recontacting. Source: Ref 69

Fig. 15 Schematic of two adjacent restorations in continuous contact. Two possible current paths shown.

occur, for example, between two amalgam restorations (Ref 70)—one a conventional amalgam and the other a high-copper amalgam—and between two gold alloys with differences in noble metal content. Other situations have already been discussed. These include a stainless steel reinforced amalgam (Fig. 8a), an endodontically restored tooth with silver cones making contact with a gold crown (Fig. 8b), and an endodontically restored tooth with steel screwposts making contact with a gold crown (Fig. 8c). Soldered appliances are also examples of dissimilar metals making continuous contact. Any multiphase microstructures are situations for galvanic corrosion to occur. Multiphase microstructures occur extensively with dental alloys.

For the amalgam-gold alloy couple making direct contact, the amalgam is the anode and suffers corrosive attack; the gold alloy is the cathode. As with galvanic couples making intermittent contact, large galvanic currents occur on first contact and decrease rapidly with time. For silver-tin amalgams, the tin from the tin-mercury phase suffers corrosion attack. The freed mercury combines with the gold of the gold alloy to form a gold amalgam that is capable of producing surface discolorations on the gold alloy. In addition to becoming corroded, the amalgam is capable of being degraded in strength by the corrosion generated by the galvanic currents (Ref 70).

Currents calculated from polarization resistance and potential differences of various contacting dissimilar metallic restorations indicate most couples to pass 1 to 5 μA on first contact (Ref 67). However, amalgam-gold alloy couples indicate a greater percentage of currents in the ranges of 6 to 10 and 11 to 15 μA . All couples initially show a sharp decrease in current with time, followed by a gradual leveling off as zero current is approached. However, disruption of surface protective films can result in increases in current at later times.

Concentration Cells

Interior-Exterior Surfaces. Because the interior surfaces of restorations adjacent to the cavity walls are exposed to extracellular fluids and higher concentrations of Cl^- than the exterior surfaces exposed to saliva, the interior instead of the exterior surfaces are more susceptible to anodic attack from Cl^- . However, if the electrons generated by the anodic oxidations are not consumed by reductions, the oxidation reactions will cease. Because the extracellular fluids have low concentrations of dissolved oxygen, corrosion of the interior surfaces would likely cease if it were not for the accessibility of electrons to the exterior surfaces exposed to saliva having a supply of dissolved oxygen from contact with the atmosphere.

Corrosion that is perpetuated by electrochemical reactions occurring on adjacent or opposite surfaces of the same restoration

constitutes an important pathway for the tarnishing and corrosion of dental alloys. This pathway is germane to amalgams as well as all types of restorations, including crowns and inlays that are cemented into the cavity preparation. In the mouth, cements are likely to become electrical conductors because the absorption of oral fluids permits the passage of ions.

Marginal Crevices. A second pathway can occur because of the seepage of salivary fluids into crevices or marginal openings formed between the restoration (especially with amalgams) and the cavity walls. The pathway is distinguished from the first in that the conditions developed in the crevice are due to diffusion and charge balances resulting from the salivary fluids instead of the extracellular fluids. Because of a lack of diffusion of the large O_2 molecule into the crevice, low O_2 concentrations result within the crevice. With time, the acidity within the crevice increases because of the accumulation of H^+ ions from the oral environment and from corrosive reactions occurring within the crevice. Chloride and other anion concentrations will also tend to increase within the crevice over time because of charge equalization. Therefore, this pathway results in conditions that are similar to the interior-exterior pathway.

Alloy Surface Characteristics. Porosities, differences in surface finish, pits, weak microstructural phases, and the deposition of organic matter can initiate corrosion by concentration cell effects. For example, gold-base alloys are known to become tarnished more easily when containing porosities and inhomogeneities (Ref 71). Rougher surface finishes of restorations generate increased corrosive conditions (Ref 72). Similarly, the pitting of base metal dental alloys of the stainless steel and nickel-chromium varieties occurs by concentration cell corrosion. Basically, the advancing pit front is free of O_2 , but the surfaces of the alloy outside the pit have an ample supply of O_2 from the air. Because the anode-to-cathode surface area is very small, the corrosion occurring at the bottom of the pit is concentrated to a very small area, thus increasing the intensity of the attack. Removal of only a small amount of metal has a large effect on advancing the pit front.

Amalgam γ_2 Phase. Deterioration of the weak, corrosion-prone tin-mercury phase (γ_2) in silver-tin amalgams has also been proposed to occur by concentration cell corrosion (Ref 66). In this model, partial removal of the γ_2 phase initially occurs by abrasion resulting from biting and chewing. After removal of the γ_2 phase has progressed to a sufficient depth, an occluded cell is formed between the bottom of the depression and the unabraded surface. Mass transport is restricted from and into the cell. The condition will approach conditions occurring in other types of concentration cells. In the present example, however, Sn^{2+} will be slowly released from the passivated γ_2 regions. The concentration of Sn^{2+} will slowly increase within the occluded cell and will be neutralized by an

equivalent amount of Cl^- by migration from the bulk electrolyte.

Consumption of O_2 within the occluded cell will take place by its utilization in the consumption of electrons by cathodic depolarization. Replenishment of O_2 will be restricted, and the concentration of O_2 within the cell will become reduced. When the solubility product of stannous oxide (SnO) is exceeded, SnO precipitates and the H^+ concentration increases. At this point, activation of the γ_2 phase occurs. Dissolution of tin occurs freely. The Cl^- concentration within the cell continuously increases to maintain electrical neutrality. Galvanic coupling of the occluded cell to the external surface generates a galvanic cell by which the cathodic reduction of O_2 occurs. Corrosion of γ_2 tin within the cell continues. Under conditions of high acidity and high concentration of Cl^- , the formation of insoluble tin chloride hydroxide ($\text{Sn}(\text{OH})\text{Cl} \cdot \text{H}_2\text{O}$) becomes thermodynamically possible.

Oral Corrosion Processes

Whether corrosion is occurring between microstructural phases of a single restoration, between components having different environmental concentrations, or between individual restorations of different compositions and making intermittent or continuous contact, the corrosion processes involved consist of oxidation and reduction. The dissolution of ions is involved with the anodic reaction, and the consumption of electrons is involved with the cathodic reaction. The slowest step in the complete chain of events controls the overall corrosion rate. Corrosion of alloys in the mouth can be viewed as being the result of corrosive and inhibiting factors (Ref 73). Some corrosive factors consist of Cl^- (in most instances), H^+ , S^- (at times), O_2 , microorganisms, and the clearance rate of corrosion products from the mouth, while some inhibiting factors consist of protein and glycoproteins (in most instances), $\text{CO}_2/\text{HCO}_3^-$ buffering system, $\text{PO}_4^-/\text{PO}_4^{2-}/\text{PO}_4^{3-}$ buffering system, and salivary flow rate.

Corrosive Factors

Chloride. The effect of Cl^- on the deterioration of passivated surface films on stainless steel, nickel-chromium, and cobalt-chromium alloys is well known. The susceptibility to pitting attack is increased. Increased Cl^- content also increases the attack of corrosion-prone phases in amalgam, other base metal alloys, and the low noble metal content alloys. Because the Cl^- concentration in saliva is about seven times lower than that in the extracellular fluids, the corrosiveness of Cl^- in saliva is usually less. Figure 16 illustrates the effect of Cl^- concentration on the polarization of amalgam by comparing the cyclic voltammetry in deaerated artificial saliva to that in Ringer's solution.

Increases in Cl^- concentrations are also likely to occur in crevices, such as the interfaces between cavity walls and adjacent surfaces of restoration. The Cl^- concentration within crevices is expected to increase to preserve electrical neutrality from the increase in Sn^+ concentration resulting from the γ_2 tin and γ_1 corrosion (Ref 66).

Chloride is capable of generating numerous compounds as products of corrosion. Chloride combines with zinc, tin, copper, silver, and others contained in dental alloys. Some of the products formed include zinc chloride (ZnCl_2), stannous chloride (SnCl_2), stannic chloride (SnCl_4), SnCl compounds such as hydrated $\text{SnOHCl} \cdot \text{H}_2\text{O}$ and $\text{Sn}_4(\text{OH})_6\text{Cl}_2$, copper chloride (CuCl), cupric chloride (CuCl_2), complex hydrated cupric chloride ($\text{CuCl}_2 \cdot 3\text{Cu}(\text{OH})_2$), and silver chloride (AgCl). The solubilities are high for all compounds, except CuCl , AgCl , and the basic tin and copper chlorides. Many additional compounds are to be considered for a complete listing of all potential corrosion products that form from dental alloys. Certainly, the chlorides of indium, gallium, beryllium, iron, nickel, chromium, cobalt, and molybdenum should be included.

Hydrogen Ion. The pH in the mouth can vary from about 4.5 and lower to about 8. In addition to the normal variations in pH of saliva due to human factors (see the section "Oral Fluids" earlier in this article), increased acidity can also result from a number of additional factors, such as the operation of crevice corrosion conditions, the acid production by dental plaque, and the effects of food, drink, and atmospheric conditions. The operation of crevice conditions in amalgams can increase acidity to well below a pH of 4. For amalgams, this acidity is mostly the result of the oxidation of γ_2 and γ_1 tin in aqueous solution. Under these conditions, the freed H^+ will become the cathodic depolarizers. With this increased acidity, dissolution of the tooth structure is also likely to occur. Calcium and phosphorus are likely to be dissolved from enamel and dentin. Dental plaque acid is produced by the fermentation of carbohydrate by microorganisms (Ref 13, 14). Most

Fig. 16 Anodic polarization at 0.03 V/min of low-copper amalgam (Microalloy) in artificial saliva and Ringer's solution. Source: Ref 74

of the fermentable carbohydrate responsible for acid production comes from the diet in the form of sugars or starchy foodstuffs.

Figure 17 shows a schematic Stephan pH test curve of plaque. Stephan showed that the pH for all plaques decrease in value following a sugar challenge (Ref 13). This means that the production of acid by fermentable carbohydrate is greater than the rate at which acid can be removed. As time proceeds, the pH again rises. For caries-free and caries-active individuals, the qualitative shapes of Stephan pH curves are similar; however, the relative position of the curve for caries-active individuals is shifted to values in pH of 4.5 and lower. Depending on the source of the sugar challenge, the pH minimum on the Stephan pH curves have been shown to remain for a number of hours (Ref 15). Even though no data are available to show the effect of plaque pH value on the tarnishing and corrosion of dental alloys, it follows from first principles that the reduction in pH will adversely affect tarnishing and corrosion resistance. Metallic restorations can become severely deposited with plaque and organic matter, as shown in Fig. 18.

Sulfide compounds, such as silver sulfide (Ag_2S), cuprous sulfide (Cu_2S), and cupric sulfide (CuS), have very low solubility product constants and often constitute the tarnished films on dental alloys. Mercury and tin sulfides may also be present when amalgams are considered. The formation of thin insoluble films occurs with very small amounts of formed corrosion products, especially on the higher noble metal content alloys. In spite of even microgram quantities of tarnishing products at times, surface discolorations can still occur and elicit unsatisfactory personal responses. Tarnishing products under these conditions almost always maintain biocompatibility with the alloy system. With

Fig. 17 pH versus time responses (Stephan curves) of plaque from caries-active (B) and caries-free (A) groups following a sugar challenge. Source: Ref 13

the lower noble metal content alloys, however, increased quantities of corrosion products can form, and tarnishing and corrosion can become more involved.

The corrosion potentials for many dental alloys in sulfide-containing solutions are often lower than the standard reduction potentials for the formation of the metal sulfides—an indication that the metal sulfides are thermodynamically stable. In some instances, particularly with amalgams, dissolution rates increase with S^{2-} concentrations. This is probably due to the increased solubility for some of the sulfides (for example, Sn_2S_3 with amalgams) to form complexes with other species. Dietary factors are the main source for increasing S^{2-} levels in saliva. Some foods, such as eggs and fish, as well as some drinking waters, are high in sulfur. Smokers have higher SCN^- saliva concentrations than nonsmokers (Ref 76). Sulfate-reducing bacteria may also generate S^{2-} in the mouth. Hydrogen sulfide that is produced in the crevicular fluid and periodontal pockets can be easily dissolved in oral fluids. Atmospheric pollutants often contain high levels of SO_2 and H_2S and may influence the concentrations of S^{2-} in the oral fluids.

Dissolved oxygen participates in corrosion reactions by either depolarizing cathodic reactions or by reoxidizing disruptive passivated surface films on base metal alloys. The first case increases or perpetuates corrosion, while the second case reduces or inhibits corrosion. Oxygen depolarization occurs by the customary electrochemical redox reactions. Electrons from the anodic process are consumed by the depolarization process. For a typical restoration, the exterior surfaces are exposed to higher O_2 concentrations. Differential aeration conditions can become operative, with the outer surfaces cathodic to the anodic interior surfaces. In other situations, differential aeration cells are set up between the bottoms of pits and the surrounding surfaces. Other types of pores and porosities are also likely to generate concentration cells. In near-neutral solution that corresponds to saliva, the reaction $\text{O}_2 + 2\text{H}_2\text{O} + 4e^- \rightarrow 4\text{OH}^-$ occurs

Fig. 18 Alloy restoration after intraoral usage showing the severity of plaque buildup that can occur. Source: Ref 75

most prevalently. If a driving force exists for metal oxidation, dissolution will be perpetuated on surfaces exposed to the lower O_2 concentration.

Oxygen is involved with numerous corrosion products formed on dental alloys. The tin from the γ_1 and γ_2 phases from silver-tin amalgams generates tin oxide products. These products passivate the amalgam at potentials less negative than about -0.7 V versus SCE, as indicated by the passive regions on the anodic polarization curves shown in Fig. 16. At more noble potentials, basic tin chlorides of the type $SnOHCl \cdot H_2O$ are formed, as indicated by the large current increases on the polarization curves. For copper-containing amalgams, basic copper chlorides of the type $CuCl_2 \cdot 3Cu(OH)_2$ form. Some additional products containing oxygen that are likely to occur with the corrosion of dental alloys include SnO_2 , $Sn_4(OH)_6Cl_2$, Cu_2O , CuO , ZnO , $Zn(OH)_2$, and the oxides of chromium, nickel, cobalt, molybdenum, iron, titanium, and so on.

Oxygen is usually excluded from solutions during polarization testing with alloys. Dissolved O_2 interferes with the anodic processes. The generated anodic polarization curves obtained in O_2 containing solutions are usually cut off within the negative potential regions. For this reason, deaerated solutions are usually used to obtain entire anodic polarization curves. Passive breakdown potentials were observed to vary depending on whether aerated, deaerated, or air-exposed solutions were used (Ref 77). However, within the O_2 concentration range likely to occur for surgical implants, the anodic polarization of type 316L stainless steel in Ringer's solution was independent of oxygen concentration (Ref 78).

Microorganisms. Two types of organisms—sulfate-reducing (*Bacteriodes corrodens*) and acid-producing (*Streptococcus mutans*) bacteria—have been discussed with the corrosion of dental alloys in the mouth (Ref 73). With regard to sulfate-reducing bacteria, depolarization of cathodic sites is thought to occur by removing H^+ from the metal surface. The hydrogen is used by the bacteria for the reduction of sulfate to sulfide, such as by the reaction $SO_4^{2-} + 8H^+ \rightarrow S_2^{2-} + 4H_2O$. In the case of acid-producing bacteria, the adsorbed microorganisms on the surface establish differential aeration conditions. As the dissolution of the metal occurs underneath the deposited microorganisms, the released acidic metabolic products, which include organic acids such as lactic, pyruvic, acetic, propionic, and butyric, increase corrosion of the already-formed anodic sites. Because anodic areas are relatively small compared with the larger cathodic areas, corrosion can be severe.

The effects of dental plaque by-products from the fermentation of carbohydrates on the tarnishing and corrosion of dental alloys are probably more significant than the effect on alloy corrosion of only the microorganisms themselves.

Clearance Rate. The clearance of corrosion products from the mouth by the movement of saliva toward the back of the mouth and eventually by swallowing and replenishment affects the concentration of products in equilibrium with the metallic restorations. Therefore, a driving force for the continuation of the corrosion processes is maintained. Products of corrosion, like chemical species introduced through the diet, are cleared from the mouth by binding the exterior surfaces of the oral mucosa to the salivary glycoproteins and mucopolysaccharides lining. Detailed information on the binding ability of corroded metallic ions to proteins in human saliva can be found in Ref 40, 41, and 79.

Alloy Factors. Although the effects of alloy selection on tarnish and corrosion behavior are considered in more detail in the section "Tarnish and Corrosion under Simulated or Accelerated Conditions" later in this article, some of the important factors are mentioned here. Alloy composition and microstructure are probably the two most important factors. The corrosion resistance of dental alloys is the result of nobility in composition or the protectiveness of oxide films formed on base metal alloys. Multiphase microstructures are capable of exhibiting increased tarnish and corrosion because of the galvanic coupling of the individual components. The heat treatment state of cast alloys has an important influence on corrosion resistance (Ref 80). Surface state or finish also influence corrosion; furthermore, cast restorations with burnished margins are more susceptible to corrosion because of differences in surface cold-worked states.

Inhibiting Factors

Organics in the form of microorganisms and plaque usually have an accelerating effect on the tarnishing and corrosion of dental alloys (see the earlier sections "Effect of Saliva Composition on Alloy Tarnish and Corrosion" and "Oral Corrosion Processes"). Organics in the form of amino acids, protein, and glycoproteins have received mixed reports. For the amino acids, the building blocks of proteins, the passivation of copper was shown to be improved in Ringer's solution with added cysteine, while nickel became more corrosion prone (Ref 81). Alanine had little effect. For Ti-6Al-4V, the amino acids proline, glycine, tyrosine, and others that constitute many salivary proteins were again shown to have very little effect.

For the plasma proteins, which simulate the organic content in blood and which simulate dental and surgical implant applications more closely, additional evidence can be found implicating the effect of proteins on corrosion behavior. For example, the corrosion rates of cobalt and copper powders increased significantly when exposed to saline solutions with albumin and fibrinogen (Ref 82); however, for chromium and nickel powders, only slight increases occurred, and for molybdenum,

decreases occurred. Corrosion of stainless steel by applied external currents was shown to be increased when conducted in saline with added calf's serum (Ref 83). For a copper-zinc alloy, the cyclic voltammetry was reported to be altered by addition of plasma proteins and plasma concentrations to a phosphated physiological saline solution (Ref 84). Albumin and γ -globulin generated increased passivation currents, while fibrinogen generated decreased critical current densities. The anodic polarizations prior to the onset of critical current densities were also shifted to more active behavior in the protein solutions. Finally, the pitting potential for aluminum increased slightly in human plasma, and current-time transients were shifted to lower values in plasma (Ref 85).

Carbon Dioxide/Bicarbonate Buffering System. The major buffering system in saliva is the CO_2/HCO_3^- system, which has been found to inhibit corrosion processes on dental alloys. Inhibition results from the deposition of such elements as copper, zinc, and calcium as carbonate films. Carbon dioxide, above all other gases, is contained most abundantly in saliva. Up to about 150 vol% (≈ 3000 ppm) is contained in vigorously stimulated saliva. The equilibrium concentration of HCO_3^- in saliva is identified by the redox reaction:

and with its equilibrium constant pK equal to (Ref 49):

$$pK = 7.9 = -\log \frac{[(H^+)(HCO_3^-)]}{p_{CO_2}} \quad (Eq\ 4)$$

At a pH = 7 and rearranging terms yields:

$$\frac{p_{CO_2}}{HCO_3^-} = 7.9 \quad (Eq\ 5)$$

Equation 5 states that the partial pressure, p , of CO_2 in units of atmospheres is 7.9 times larger than the HCO_3^- concentration in mol/L. Therefore, for p_{CO_2} of the order of 0.07 atm, HCO_3^- concentrations of the order of 0.009 mol/L are formed. This shows that relatively large concentrations of HCO_3^- can be made available in saliva to form carbonates with cations released from corrosion reactions on dental alloys and with other cations found in the mouth, such as calcium.

Many of the different carbonates likely to form are insoluble in aqueous solution. The calcium carbonates are known for making waters hard. Compounds of this type being deposited as thin-film tarnish and corrosion products on dental alloys are very likely to interfere with the corrosion activity. Deposition over cathodic sites effectively increases corrosion resistance by increasing resistance to depolarization reactions. Because the films of carbonates are also likely to increase the contact resistances between electrodes and saliva, galvanic-corrosion processes are likely to change from purely corrosion control to at least partial ohmic control. Under

these conditions, local anodes and cathodes may change in order to maintain lower-resistance paths for both ionic and electronic conduction. For example, the *in vivo* tarnishing of several silver-palladium alloys was shown to be due to the galvanic coupling between microstructural phases located very close to each other on the alloy surface (Ref 86).

Phosphate Buffering System. A secondary buffering system in saliva, the $\text{PO}_4^-/\text{PO}_4^{2-}/\text{PO}_4^{3-}$ system, has also inhibited the corrosion of dental alloys. The progressive inhibition of amalgam corrosion activity in a chloride solution (10 millimolar NaCl) was shown to occur with increasing added phosphate concentrations (Ref 73). A 15 millimolar phosphate addition retarded the anodic polarization almost entirely, while concentrations of 10, 7.5, and 1 millimolar generated anodic current peaks of about 2.5, 3.0, 3.5, and 6.0 $\mu\text{A}/\text{mm}^2$, respectively. The 10 millimolar NaCl solution, without phosphate, generated a continuous increase in current, to much larger values. No passivation occurred within the potential range used.

For tin in neutral phosphate solutions, a passive film forms by precipitation or by a nucleation and growth process (Ref 87). Tin phosphate, basic tin phosphate complexes, and tin hydroxides are formed.

Salivary Flow Rate. Increasing the salivary flow rate increases the concentration of most buffering species in saliva. This tends to inhibit corrosion. The organic content, the $\text{CO}_2/\text{HCO}_3^-$ content, the $\text{PO}_4^-/\text{PO}_4^{2-}/\text{PO}_4^{3-}$ content, pH, and the Ca^{2+} content all increase with flow rate; however, only the increases in Cl^- concentration promote corrosion. Figure 9 shows the effect of flow rate on the concentration of a number of species.

Overview. Saliva acts as an ocean of anions, cations, nonelectrolytes, amino acids, proteins, carbohydrates, and lipids, flowing in waves against and into dental surfaces, with a diurnal tide and varying degrees of intensity (Ref 88). Whether tarnish and/or corrosion of dental metallic materials will occur cannot be categorically stated. It has been discussed that the degree to which dental alloy corrosion occurs in the mouth is dependent on the oral environmental conditions for each person. In addition to effects from the dental alloy itself, competition between corrosive and inhibitory factors of the oral environment will dictate whether corrosion will occur and to what extent. In addition to the aforementioned factors, still others have been isolated and should be included for a more complete assessment of the overall corrosiveness or protectiveness of the oral environment (Ref 73).

Nature of the Intraoral Surface

The composition and characterization of biofilms, corrosion products, and other debris that deposit on dental material surfaces are

discussed in this section. As will be shown, the nature of these deposits is dependent on the substrate material (enamel, alloy, porcelain, and so on).

Acquired Pellicles

Characteristics. Most surfaces that come into contact with saliva, including metallic, polymeric, and ceramic dental materials, as well as enamel, interact almost instantaneously with proteins and glycoproteins to form a bacteria-free biofilm of the order of several nanometers in thickness (Ref 89–91). This most intimate layer of organic matter adsorbed to the substrate material is called the acquired pellicle. A fourier transform infrared spectroscopy spectra of the surface of a low-gold dental crown and bridge alloy after *in vivo* exposure is shown in Fig. 19. Detection for protein, carbohydrate, and lipid is indicated. Thicknesses of the films increase only slightly with longer exposure times. The pellicles, in contrast to enamel and most dental alloys, are for the most part acid insoluble, although an acid-soluble fraction also occurs. The films are diffusion barriers against acids, thus reducing the acid solubility of enamel and metallic materials and inhibiting, or at least reducing, the adherence of organisms (Ref 92, 93).

Composition. Chemical analysis of 2-h pellicles formed on enamel indicated abundant amounts of glycine, glutamic acid, and serine (Ref 94). Carbohydrate contents of similar pellicles formed to enamel were found to contain about 70% glucose, with a number of other sugars and small molecules. Acidic proline-rich phosphoproteins have also been identified from *in vivo* enamel pellicles (Ref 95). The proline-rich proteins constitute as much as about 37% of the total proteins in new pellicles within the first hour. However, there is a gradual degradation beginning after about 24 h that is reflected

by the fact that the proline-rich protein content in aged pellicles is less than 0.1%.

Substrate Effects on Pellicle Composition. Chemical analysis of the pellicles formed on several plastics and glass showed that the amino acid content varied and was different from that formed on enamel (Ref 96). It was concluded that the chemical composition of the substrate has an important influence on the type of proteins that become adsorbed. For the pellicle formed on dentures, it was concluded that a specific mechanism was controlling the deposition of protein and that specific proteins seemed to be precursors in forming the film (Ref 97). Isoelectric focusing of the extracted proteins adsorbed from a human saliva preparation onto a number of different powder substrate compositions, including palladium, silver, copper, silver-copper, tin, silver-tin-copper alloy, bismuth, polymethyl methacrylate, porcelain, hydroxyapatite, and enamel, indicated that the same three to four proteins appeared to be involved with the adsorption process on all substrates regardless of composition (Ref 41). Therefore, from this study, substrate composition appeared not to affect the type of proteins becoming adsorbed.

Binding Mechanisms. The binding of salivary macromolecules to surfaces has been proposed to consist of electrostatic interactions between the charged groups in the molecule and the surface charges on the substrate (Ref 98). For enamel, only the hydroxyapatite, and not the organic matrix, contributes a surface charge for binding. Because the negatively charged phosphate group comprises about 90% of the surface area of hydroxyapatite, the phosphate group rather than the calcium ions will be the primary binding sites. The hydration layer contains soluble calcium and phosphate ions as well as soluble cations and anions. Because the salivary molecules adsorbed to enamel are mainly acidic, binding to the negatively charged

Fig. 19 Fourier transform infrared spectroscopy spectra from surface of a crown and bridge alloy (Midas) after several weeks of intraoral usage. Amide I and II are protein. Additional smaller peaks at 1375 and 1425 cm^{-1} are also protein.

phosphate group appears to occur through a divalent cation, such as calcium. Phosphorylated and sulfated acidic proteins show a high affinity for hydroxyapatite. A direct replacement of the protein phosphate group and the phosphate in hydroxyapatite is also likely (Ref 99).

Direct binding to the calcium surface ions in enamel will also occur, but will be limited because of the relatively small surface area fraction occupied by the calcium ions. Adsorption of salivary proteins to metals may again occur through a divalent cation. The negative charges in the acidic proteins are likely to be bound to the negative anodic surface sites on the metal surface by the bridging cation. Additional information on protein binding and analyses of variations in protein binding to a metal surface through differential scanning calorimetry can be found in Ref 100.

Plaque, Corrosion Products, and Other Debris

Integument. In addition to the thin acquired biofilms, aged pellicles contain microorganisms or plaque, mineralized products, corrosion products, and other debris all commonly referred to as dental calculus. Calculus, which is a by-product of the reaction between microorganisms and calcification, may form in abundance in some environments. Calculus does not form directly onto teeth or other materials. It is deposited or adsorbed onto the acquired pellicle. The combined surface coating, including the adsorbed pellicle, plaque, and calculus, which includes organic matter and any released ions or corrosion products generated by the substrate, is often referred to as the integument.

Substrate Effects on Integument Characteristics. A study was made of the effect of the restorative material type on plaque composition (Ref 101). The carbohydrate/nitrogen ratios (CHO/N) were similar for amalgam, gold inlay, gold foil, and resin. Plaque analyzed from freshly placed restorations had CHO/N = 1; this value increased to 1.3 and 1.2 at 3 and 6 months, respectively, and decreased to 0.5 at 1 year and for old restorations. It was proposed that the variation in plaque carbohydrate content with the age of the restoration was due to corrosion or to the absorption of impurities into surface porosities and pits. These mechanisms are supported by the data generated with silicate restorations. This was the only material to show significant differences in CHO/N. The CHO/N was 1.0 at 1 year. This suggests that the carbohydrate is metabolized less efficiently by the silicate. It is known that silicate restorations leach fluoride with time. Therefore, the fluoride acts as an enzyme inhibitor.

The thicknesses of the integuments formed in the mouth vary and may depend on the substrate material. For example, sputtering times in Auger electron spectroscopy (AES) depth profiling required only 0.3 min to reach the amalgam substrate, while 2.4 min was required

to reach the gold alloy substrate (Ref 91). Carbon, nitrogen, and oxygen were distributed in much the same manner as films formed on different substrates. The main difference between the integuments formed on the amalgam and on the gold alloy was the presence of tin ions with the amalgam and the presence of copper ions with the gold alloy. The release of substrate ions is likely to interact with the attachment of microorganisms and therefore with the metabolism of plaque.

Substrate Corrosion. Corrosion reactions involve diffusion of ions—whether cations from oxidations or dissolved O_2 and H^+ for reductions—through the formed integument. The surface coating has the ability to act as a diffusion barrier to the movement of ions. Released ions are likely to become complexed, or bound, to the proteins and glycoproteins constituting the integument and free native proteins in the bulk saliva, provided diffusion is not restricted by the integument. Insoluble corrosion products of the oxides, chlorides, sulfides, carbonates, phosphates, and so on have the capability of being deposited at the alloy/film interface or becoming an integral part of the integument. Soluble products, in addition, may be released into the bulk saliva.

For one dental restorative alloy, it was shown that the polarization resistance of the alloy increased with protein concentration, while at the same time, the concentration of soluble species in solution also increased (Ref 63). This situation was explained by the increased effect of proteins in solubilizing corrosion products. Energy-dispersive spectroscopy (EDS) spectra of the corroded surfaces showed reduced peak intensities for chlorine and sulfur on surfaces exposed to the proteins. Therefore, even though the severity of corrosion is less in protein-containing solutions, increased levels of soluble products are still generated.

In Vivo Tarnished Film Compositions. Auger thin-film analysis of the surfaces of dental alloys with varying compositions and after functioning in the mouth indicated that the tarnished films were due to chemical reactions between alloy and inorganic species and to the adsorption and deposition of organic matter (Ref 43). Carbon was the dominant nonalloying element by about six times, followed by oxygen, calcium, nitrogen, chlorine, sulfur, magnesium, silicon, phosphorus, aluminum, sodium, and tin. Of the elements from the alloy itself, copper was dominant. In a microprobe analysis of in vivo discolorations on gold alloys, both silver sulfides and copper sulfides were detected, depending on the composition of the alloy. Sulfur was found isolated and carbon was present in greatest quantities (Ref 102).

Intraoral (In Vivo) versus Simulated (In Vitro) Exposures

Need for Laboratory Testing. The tarnish and corrosion behavior of dental alloys under

actual oral environmental conditions is required. However, except for selected clinical trials, the initial testing of new and improved alloys for tarnish and corrosion resistance is usually carried out under laboratory conditions in either simulated or accelerated tests. This is so because of:

- The possible human exposure to harmful species
- The variability in the oral environmental conditions from person to person and even with the same person from location to location and with time
- As a result of the variability in the oral environment, the inability to follow the effects on tarnish and corrosion from changes in parameters in alloys and in solution

Most laboratory tests use an artificial saliva or a physiological saline solution, such as Ringer's solution (Table 3), diluted Ringer's solution, various concentrations of NaCl, and various concentrations of Na_2S . The main deficiencies with these solutions is that the nonelectrolytes, including the proteins, glycoproteins, and microorganisms, are not included. This fails to produce the pellicle and integuments on laboratory samples that otherwise would have formed on all intraoral surfaces.

In spite of these shortcomings, for the most part, the inorganic salt solutions have become indicators for the aggressiveness of the oral environment. However, the inability to correlate in vivo to in vitro behaviors in some instances is likely because of the failure to account for the shortcomings (Ref 86).

The use of solutions with higher-than-normal concentrations accelerates the tarnish and corrosion processes. For example, 3200 immersions of 15 s/min duration in a 5% Na_2S solution with a Tuccillo and Nielsen tarnishing apparatus (Ref 103) is estimated to simulate 12 months of actual in-service use (Ref 104). Ringer's and 1% NaCl solutions, which contain about seven times the Cl^- concentration of human saliva, are used in anodic polarization tests to amplify peaks in current behavior (Ref 60, 61). Corrosion of conventional amalgams in Ringer's or 1% NaCl generates products that are morphologically similar to those from retrieved amalgams after intraoral use (Ref 105, 106).

A comparison of the tarnishing of three gold alloys, both in vivo and in vitro, indicated that the cyclic immersions in a 5% Na_2S -air environment predicted with considerable reliability the relative susceptibility for the alloys to tarnish (Ref 107). The tarnishing of 81 gold-silver-palladium alloys also indicated accelerated laboratory exposures in Na_2S solution simulated in vivo use (Ref 108). In vivo and in vitro (Na_2S solutions) tarnishing of gold alloys in Na_2S solutions has shown the same microstructural constituents to be attacked (Ref 109, 110). Silver- and copper-rich lamellae were the constituents exhibiting sulfide deposits.

Artificial Solutions in Corrosion and Tarnish Testing. As already indicated, the interior surfaces of restorations are exposed to the

interstitial fluids and the exterior surfaces to the salivary fluids. A physiological saline solution such as Ringer's, which contains a Cl^- concentration of about seven times larger than artificial saliva, is therefore more appropriate for simulating in vivo interior surfaces in laboratory testing methodologies. The O_2 content should be reduced to simulate in vivo levels in dentin. The use of Ringer's and even higher Cl^- concentrations is appropriate for the testing of corrosion that may occur within marginal crevices of restorations because crevices can become chloride-rich and acidified. However, applying these results to the corrosion occurring on exterior surfaces of restorations may not be appropriate, even when considering that the increased Cl^- corrosion with Ringer's solution would be an even more stringent test and that the results would correspond to maximum corrosion conditions.

An artificial saliva is more appropriate for testing the corrosion of the exterior surfaces of restorations. The artificial saliva should take into account most of the species contained in saliva and not just a selected few that have been known to affect alloy corrosion. The artificial saliva should include the capabilities for generating organic films on the surfaces, even though their effects in isolated tests may prove unimportant. In order to simulate oral environment conditions, the tarnishing of the exterior surfaces of restorations, an artificial saliva incorporating sulfide is appropriate. Even though the normal sulfide concentrations contained in saliva are within low ranges, accumulations of sulfide can occur along and within crevices to justify the use of higher than normal concentrations. However, the sulfur peak intensities detected with secondary ion mass spectroscopy (SIMS) on alloy surfaces exposed to low levels of sulfide solutions were similar to those from solutions containing higher sulfide concentrations. However, the alloy surface color changes responded more to higher sulfide concentrations.

Classification and Characterization of Dental Alloys

As indicated in the introduction to this article, a wide range of dental alloys exist. This selection reviews the following types of alloys available for dental applications:

- Direct filling alloys
- Crown and bridge alloys
- Partial denture alloys
- Porcelain fused to metal alloys
- Wrought wire alloys
- Soldering alloys
- Implant alloys

The effects of composition and microstructure on the corrosion of each alloy group are discussed in this section. Additional information on tarnishing and corrosion behavior of these

alloys is discussed later in the section "Tarnish and Corrosion under Simulated or Accelerated Conditions" in this article.

Direct Filling Alloys

Amalgams. Two types of amalgams are used: low copper (referred to as conventional) and high copper. The alloy particles of the low-copper type are all of the single-particle variety, whereas the high copper type can also be of the dispersed particle variety.

Amalgams are produced by combining mercury with alloy particles by a process referred to as trituration. About 42 to 50% Hg is initially trituated with the high-copper types, while increased quantities of mercury are used with the low-copper types. High-speed mechanical amalgamators achieve mixing in a matter of seconds. The plastic amalgam mass after trituration is inserted into the cavity by a process of condensation. This is accomplished by pressing small amalgam increments together until the entire filling is formed. For amalgams using excess mercury during trituration, the excess mercury is condensed to the top of the setting amalgams mass and scraped away. American National Standards Institute (ANSI)/American Dental Association (ADA) Specification No. 1 Alloy for Dental Amalgam details standard requirements for chemical composition, physical properties, mass, foreign material, and loss of mercury for alloys used in the preparation of dental amalgam (Ref 111).

Low-Copper Conventional Amalgams. The alloy particles with the low-copper type are basically Ag_3Sn , the γ phase of the Ag-Sn system, even though smaller amounts of the β phase, a phase richer in silver, may also be present. Copper can be added in amounts up to about 5 wt% and zinc up to 1 to 2%. About 2 to 4% Cu is soluble in Ag_3Sn , while the additional copper usually precipitates as Cu_3Sn , the ϵ phase of the Cu-Sn system, although amounts of Cu_6Sn_5 , the η' phase, may also occur. The low-copper particles are mostly lathe cut irregular, although spherical atomized particles are also used. The amalgamation reaction for a low-copper amalgam is:

In Eq 6, Ag_3Sn with Cu_3Sn and zinc react with mercury to form two major reaction products of $\text{Ag}_{22}\text{SnHg}_{27}$ (the γ phase of the Ag-Hg system with dissolved tin and referred to as the γ_1 amalgam phase) and Sn_8Hg (the γ_2 amalgam phase) (Ref 112). Unreacted Ag_3Sn with Cu_3Sn and zinc particles are held together in a γ_1 matrix with γ_2 interspersed within the matrix. Typical distributions of the phases range up to about 30 wt% for γ , 60 to 80% for γ_1 , 5 to 30% for γ_2 , and up to about 3% for ϵ (Ref 113). Very minimal η' may also form. Zinc is generally distributed

uniformly throughout material. Porosities are in all amalgam structures. As high as 6 to 7 vol% occur with some systems (Ref 114). Interconnection of the γ_2 phase throughout the bulk may also occur (Ref 115). Transformation of the $\gamma\text{Ag}-\text{Hg}$ (γ_1 amalgam phase) to the $\beta\text{Ag}-\text{Hg}$ phase (β_1 amalgam phase) can also occur with aging (Ref 116). However, because of the dissolved tin in the γ_1 structure, stability is increased. Figure 20 presents the microstructure of a polished low-copper amalgam showing the γ , γ_1 , and γ_2 phases and some porosity.

High-Copper Amalgams. The alloy particles with the high-copper dispersed-phase type are blends of conventional particles with basically spherical silver-copper eutectic particles in the proportion of about 3 to 1, respectively. The dispersed particles can be composed of a variety of silver-copper compositions, with other alloying elements, and combined in varying proportions with the conventional particles.

The alloy particles with the single-particle high copper are compositions that can contain up to 30% Cu and more. The particles are mostly atomized into spherical shape.

The setting reaction for high-copper dispersed phase amalgam is:

and for high-copper single-particle amalgam is:

For dispersed-phase amalgam, γ initially reacts with mercury to form γ_1 and γ_2 phases, as with the low-copper amalgam. However, an additional reaction occurs between γ_2 and the silver-copper particles to form η' and additional γ_1 . The η' phase forms reaction rings around the dispersed particles as well as islands of reaction

Fig. 20 SEM micrograph of polished, etched, and partially repolished low-copper amalgam (minimax). A, γ ; B, γ_1 ; C, γ_2 ; D, porosity

phase within γ_1 matrix. Figures 21 and 22 present the microstructure of a dispersed-phase amalgam and EDS x-ray mapping for silver, mercury, tin, and copper, respectively.

For single-particle high-copper amalgam, reaction of the initially formed γ_2 phase occurs with the ϵ phase of the original alloy particles

Fig. 21 SEM micrograph of polished, etched, and partially repolished high-copper dispersed-phase amalgam (Cupralloy). A, γ ; B, Ag-Cu; C, γ_1 . See also Fig. 22.

instead of with a dispersed particle to form the η' phase again. The γ_1 phase is likely to become tin enriched. Reaction zones around the original alloy particles, as well as products within the matrix, occur.

Figure 23 shows the microstructure of a polished, etched, and slightly repolished high-copper single-particle amalgam that shows primarily the distribution of the η' phase. The elimination of γ_2 phase and the subsequent formation of ϵ phase are time dependent and are dependent on the amalgam system (Ref 117). For fast-reacting amalgams, formation of η' may be complete within hours, while for slower-reacting systems, η' may continue to form for months. The single-particle high-copper amalgams contain higher percentages of the η' phase and lower percentages of the γ_2 phase, although all high-copper amalgams contain minimal γ_2 relative to conventional amalgams. Porosities with the high-copper amalgams can be up to approximately 5 vol% and with a smaller size distribution than with the conventional type (Ref 114). The γ_1 to β_1 transformation can also occur to a limited extent. With the high-copper amalgams, both indium (5%) and palladium (0.5%) containing amalgams add specific characteristics to the amalgams and have gained limited use.

Crown and Bridge and Partial Denture Alloys

Noble Dental Alloys. Noble metals have traditionally been used as dental casting alloys for their relative inertness in the oral environment. The metals that are considered to be noble differ depending on the source; however, typically, for dental applications, the noble metals are gold and the platinum-group metals (platinum, palladium, iridium, ruthenium, osmium, and rhodium). Because the alloying of silver with specific amounts of iridium can make it resistant to tarnish and corrosion, many also consider silver to be a noble metal (Ref 118). Historically, the noble dental casting alloys have consisted of alloys with greater than 75 wt% Au and metals of the platinum group, as indicated in the *Composition* requirement section of the 1966 edition of ANSI/ADA Specification No. 5 for "Dental Casting Gold Alloy" (Ref 119). This requirement was based on a belief that to attain acceptable corrosion and tarnish resistance in the oral cavity, dental casting alloys had to comprise at least this minimum percentage of noble metals. This belief was reflected by the fact that before 1969, over 95% of the fixed dental prostheses sold in the United States were made of alloys with a minimum of 75 wt% Au and other noble metals; however, in this same year, the United States government ended its support on the price of gold, placing it on the free market, and by the early eighties, the price of gold had increased from around \$35 per ounce to over \$400 per ounce (Ref 120). This created an impetus for the development of alternative alloys that used less gold and other noble metals. Eventually, advances in metallurgy yielded dental casting alloys with gold contents of less than 50 wt% that could exhibit acceptable corrosion and tarnish behavior in the oral environment (Ref 118). The clinical success and widespread use of these lower-cost alloys in dentistry prompted the revision of ANSI/ADA Specification No. 5 in 1989 (Ref 121). The revised

Fig. 23 SEM micrograph of polished, etched, and partially repolished high-copper amalgam (Sybralloy). A, alloy particles; B, γ_1 ; C, η'

specification dropped the compositional requirements, removed the word “gold” from the title, and suggested both a corrosion and tarnish test, which then became requirements in a further revision in 1998 (Ref 122). For the purpose of dental procedure codes, the ADA classifies “high noble” and “noble” dental casting alloys as follows (Ref 123):

- **High noble:** noble metal content (gold and metals of the platinum group) ≥ 60 wt% and gold ≥ 40 wt%
- **Noble:** noble metal content (gold and metals of the platinum group) ≥ 25 wt%
- **Gold-base:** must contain ≥ 40 wt% Au and gold must be the major element of the alloy

This classification system is also supported by the Identallory Council, which is a group (formed in 1986) comprising the major dental materials manufacturers. Table 4 shows the compositions of some common gold-base dental alloys.

The high noble dental alloys for cast applications are primarily based on the gold-silver-copper ternary, with additions of palladium, platinum, and zinc, as well as grain-refining elements, such as rubidium and iridium. For the

most part, the properties of the high noble dental alloys follow similar patterns as those shown by the gold-silver-copper ternary alloys, although the additional alloying elements in the dental alloys have significant effects on properties. Because the high noble alloys have relatively small liquidus-solidus gaps, casting segregations, inhomogeneities, and coring effects are not major problems. Microstructurally, single-phase structures predominate because compositions fall within the single-phase region of the Au-Ag-Cu system. Grain refinement by the noble metal additions of ruthenium and iridium decreases grain sizes 20 to 50 μm (0.8 to 2 mils) and increases strengths and elongations by about 30 and 15%, respectively (Ref 124).

The primary hardening mechanism in gold-base dental alloys is by disorder-order superlattice transformations of the Au-Cu system. The ordered domains of the Au-Cu system also extend into the ternary phase Au-Ag-Cu regions. Typically, heat treatment times and temperatures are 15 to 30 min at 350 to 375 °C (660 to 705 °F). Often, it is adequate to bench cool the casting in the investment after casting to gain hardness. Because of the complexity of the dental gold alloy compositions, the exact hard-

ening mechanisms depend on the particular composition of the alloys. Table 5 presents a schematic representation of the age-hardening mechanisms and related microstructures occurring in gold dental alloys. Included are representations for high-gold alloys (HG), low-gold alloys (LG), gold-silver-palladium-base alloys (GSP), and 18 karat and 14 karat gold alloys. Five types of phase transformations are found (Ref 125):

- The formation of the AuCu I ordered platelets and twinning characterized by a stair-step fashion
- The formation of the AuCu II superlattice with periodic antiphase domain structure
- The precipitation of the PdCu superlattice with face-centered tetragonal structure analogous to the AuCu I
- Spinodal decomposition giving rise to a modulated structure
- The formation of the lamellae structure developed from grain boundaries by discontinuous precipitation

The noble metal alloys comprise a wide variety of compositions. Gold-, palladium-, silver-, and copper-base alloys are used. Platinum and zinc contents are usually held to several wt% maximum, if present. Microstructurally, the low-gold-content casting alloys are complex, and examination of phase diagrams of either the Au-Ag-Cu or Ag-Pd-Cu ternary systems indicates that the liquidus-solidus gaps between the various phases can be large (Ref 124). Therefore, coring and casting segregations occur upon solidification during casting. The alloys are characterized by dendritic structures combined with additional phases located within interdendritic positions. Both silver- and copper-rich segregations occur. The presence of gold, platinum, zinc, and other alloying elements further complicates the structures.

The addition of palladium and zinc to the Au-Ag-Cu alloy systems makes heat treatments to single-phase structures difficult. In silver-rich phases, the solubility limit for palladium and zinc is only about 1 to 2% at 500 °C (930 °F), while for copper-rich phases, solubilities are much higher—of the order of 10%. Therefore, precipitation of palladium- and zinc-rich phases occurs. Differences also occur in the gold contents between the phases with the copper-rich phases having the higher contents (Ref 126).

Silver-palladium-base alloys with additions of copper, gold, and zinc are also complex and contain multiple phases. Microstructurally these alloys are characterized by silver-rich matrices interspersed with Pd-Cu-Zn enriched compounds.

The hardening mechanisms associated with some of these noble alloys are shown in Table 5. In addition to the gold-copper disorder-order transformations, ordering due to the palladium-copper superlattices is also usually involved because of replacement of some of the gold by palladium.

Table 4 Compositions, yield strengths, and percent elongation for some common gold-base alloys

Base Metal Alloys. Predominantly base metal dental casting alloys are classified by the ADA, according to their noble metal content, as follows: Predominantly base—noble metal content (gold and metals of the platinum group) ≤ 25 wt%. A significant amount of the base metal alloys for metal cast crowns and bridges are composed of nickel-chromium alloys, although stainless steels are also used,

particularly outside of the United States. Nickel-chromium alloys are also used for the construction of partial dentures; however, cobalt-chromium alloys far exceed any other alloy for use in this application. Titanium alloys are also gaining popularity for dental applications.

Nickel-Chromium Alloys. The primary alloying element with the nickel-base alloys

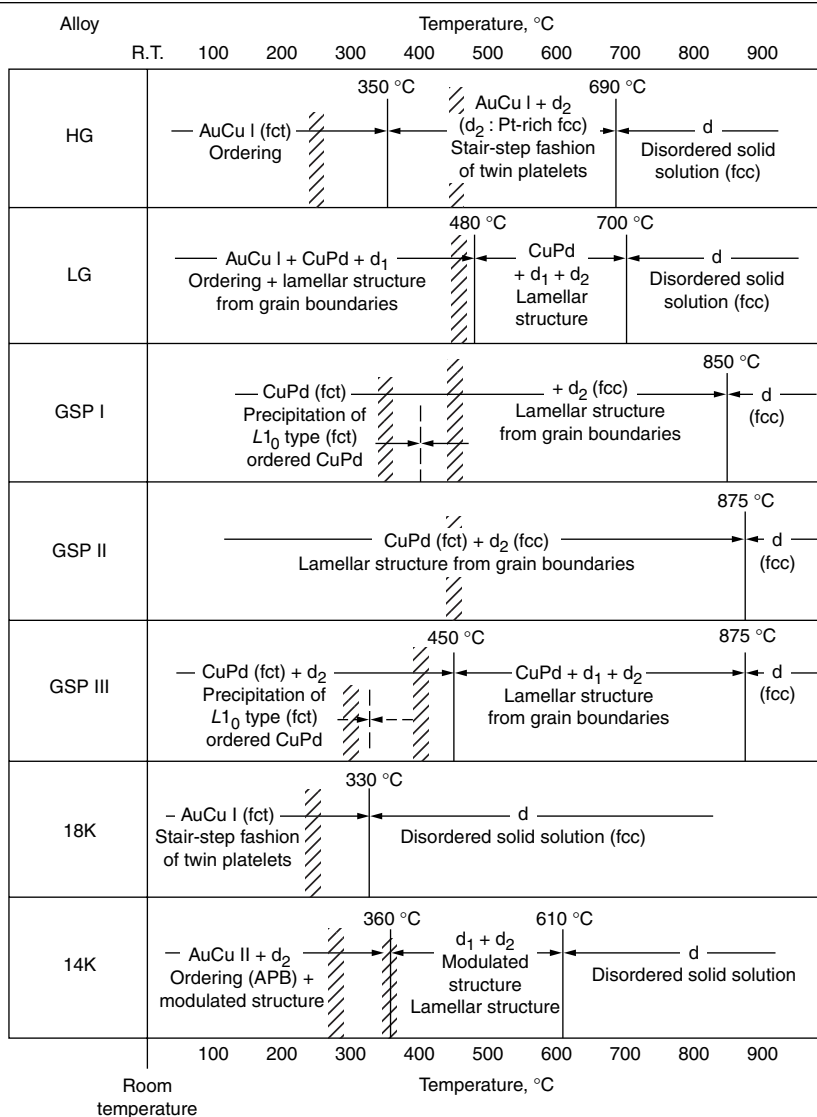

is chromium between about 10 and 20 wt%; Molybdenum up to about 10%; manganese and aluminum up to about 4% each; and silicon, beryllium, copper, and iron up to several percent each can also be added. The carbon contents range between about 0.05 and 0.4%. Elements such as gallium, titanium, niobium, tin, and cobalt can also be added. Because of differences in properties required for crown and bridge applications versus partial denture applications, minor modifications in compositions occur between nickel-chromium alloys intended for the two applications. This is reflected by the fact that crown and bridge nickel-chromium alloys contain higher percentages of iron, very minimal or no aluminum and carbon, and copper additions (Ref 127).

Chromium and molybdenum are added for corrosion resistance. In order to be effective, these elements must not be concentrated along grain boundaries. Chromium contents below about 10% deplete the interior of the grains leading to corrosion, such as pitting and crevice corrosion, and is also a solid-solution hardener. Thus, in 1993, the German Federal Health Department recommended a minimum amount of chromium and molybdenum of 20 wt% and 4 wt%, respectively, for dental surgery materials (Ref 128). Manganese and silicon are reducing agents, while aluminum also improves corrosion resistance and improves strength through its formation of intermetallic compounds with nickel. Silicon, like beryllium and gallium, lowers the melting temperature. Beryllium is also a solid-solution hardener and improves castability. Niobium, like molybdenum and iron, affects the coefficient of thermal expansion. Gallium is a stabilizer and improves corrosion resistance. The oxide-forming elements and the elements promoting good bond strength to porcelain are discussed later in the section "Porcelain Fused to Metal (PFM) Alloys" in this article.

Cobalt-Chromium Alloys. ASTM F 75 "Standard Specification for Cobalt-28 Chromium-6 Molybdenum Alloy Castings and Casting Alloy for Surgical Implants" sets the compositional requirements for chromium, molybdenum, and carbon, in wt%, as follows: 27.00 to 30.00% for chromium, 5.00 to 7.00% for molybdenum, and a maximum of 0.35% for carbon (Ref 129). Small additions of other elements, such as silicon and manganese at maximum values of 1%, iron at a maximum of 0.75%, and nickel at a maximum of 0.50%, are also sometimes present, with the balance of the alloy being cobalt. This composition forms the basis for two additional generalized compositions. The first includes a group of alloys that has been developed from the aforementioned basic composition but with each modified by the addition of one or more elements in order to obtain a particular range of properties (Ref 130). Some of these modifying elements include gallium, zirconium, boron, tungsten, niobium, tantalum, and titanium.

Table 5 Hardening mechanisms for some dental alloys

The hatched areas represent the hardness peaks on aging. °F = (9/5) °C + 32 °F.

The second generalized composition includes replacement-type alloys, with a major portion of the cobalt replaced by nickel and/or iron. The resulting composition is a cross between cobalt-base alloys and stainless steels. The effects of the individual elements on the properties of the alloys are similar to those already discussed for the nickel-chromium alloys.

Even though chromium is just one of the alloying elements in cobalt-chromium-molybdenum alloys, many studies have attributed the passivating behavior of the films that cover these alloys to the oxides of chromium (Ref 131–135). For example, using electron spectroscopy for chemical analysis (ESCA), Storp and Holm determined that a chromium-rich oxide layer had formed on a Vitallium implant (28% Cr, 6% Mo, Mn + Ni + Fe + W < 2%, balance Co) that had been immersed in water, with the chromium that was present being in the trivalent form (Ref 132). Chromium (III) oxide, Cr_2O_3 , is known to be a metal deficit (oxygen excess) oxide, or *p*-type semiconductor, under most conditions (Ref 136–140). This is significant because generally for *p*-type semiconductors, oxide growth occurs at the oxide/ambient interface, as a result of outward cation diffusion (Ref 137). Thus, oxide growth occurs at the oxide/electrolyte surface, which makes it feasible to image this oxide growth. With this in mind, in-situ electrochemical atomic force microscopy (AFM) has been performed on a cast cobalt-chromium-molybdenum alloy, relating its electrochemical behavior with its oxide structure (Ref 141, 142).

In general, cobalt-chromium alloys are hardened principally by carbide formation, and it is known that the variance in carbon composition has a great effect on carbide content. An increase in carbon from 0.05 to 0.30% will increase the carbide content from less than 2 to 5% to between 5 and 15% by volume, which will substantially increase the hardness of the alloy (Ref 143). A number of carbides have been detected in dental cobalt-chromium alloys (Ref 144), with MC , M_6C , and M_{23}C_6 being the most prominent.

Molybdenum is added to cobalt-chromium alloys as a grain refiner to produce finer grains upon casting and forging, resulting in a material with greater mechanical properties (Ref 145). Molybdenum is also added as a hardening agent, an oxide former, and to increase crevice and pitting corrosion resistance.

The scanning electron micrographs (SEMs) in Fig. 24 show an ASTM F 75 cast cobalt-chromium-molybdenum alloy with a carbon content of 0.22 wt% that was subjected to a homogenizing anneal (Ref 142). The grains range from approximately 50 to 500 μm (2 to 20 mils) in size, and the alloy contains both intragranular (at interdendritic sites) and intergranular carbide distributions, with a variety of shapes and sizes. However, thermomechanical processing of cobalt-chromium-molybdenum alloys can have a drastic effect on the microstructure, as discussed later in the section

“Cast, Wrought, and Forged Cobalt-Chromium Alloys.”

Titanium-Base Alloys. The first alloy to be successfully cast had a composition of 82Ti-13Cu-4.5Ni with a melting temperature of 1330 °C (2426 °F). The introduction of an argon/electric arc vertical centrifugal casting machine and a vacuum-argon electric arc pressure casting machine made the casting of the higher melting point titanium alloys achievable. Pure titanium and Ti-6Al-4V have been successfully cast by these latter methods (Ref 146).

Copper-aluminum alloys are also used as dental restorative materials. Compositions include the copper base, with about 10 to 20% Al, and up to approximately 10% iron, manganese, and nickel. The as-cast etched structures are dendritic.

Factors Related to Casting. Many factors determine the castability of dental alloys. Some of these factors include the casting temperature and surface tension of the molten alloy as well as many variables associated with the casting technique, some of which include wax pattern preparation, position of the pattern in the casting ring, techniques used in alloy heating, and centrifugal casting force. Some factors affecting casting accuracy include the thermal contraction of the alloy as a result of going from liquid to room temperature, the effectiveness of investment material to compensate for the thermal contraction of the alloy, anisotropic contractions, and the roughness of the casting.

Casting porosity is another important factor in the casting process. Although casting technique variables affect porosity contents, alloy composition can also affect porosity. One way in which composition affects porosity is the generation of internal shrinkage pores between microstructural phases in complex multiphase alloys. This microporosity weakens alloys, makes finishing and polishing more difficult, and is a prime factor in tarnishing. Palladium in alloys is susceptible to occluding gases from the melt. Therefore, palladium-containing alloys have the potential for becoming affected mechanically through embrittlement.

Porcelain Fused to Metal (PFM) Alloys

Stringent demands are placed on the alloy system meant to be used as a substrate for the baking on or firing of a porcelain veneer. The thermal expansion coefficients of alloy and porcelain must be matched so that the porcelain will not crack and break away from the alloy as the temperature is cooled from firing temperature to room temperature. Thermal expansion coefficients of porcelains are in the range of 14×10^{-6} to 15×10^{-6} mm/mm °C. Selection of an alloy with a slightly larger coefficient by about 0.05% is recommended so that the alloy will be under slight compression.

The alloy must have a high melting point so that it can withstand the firing temperatures involved with the porcelain. However, the temperature must not be excessively high so that conventional dental equipment can still be used. A temperature of 1300 to 1350 °C (2370 to 2460 °F) is about maximum. The porcelain firing procedures require an alloy with high hardness, strength, and modulus so that thin sections of the alloy substrate can support the porcelain, especially at the firing temperatures.

High mechanical properties are also required for resisting sag of long span bridge unit assemblies during firing. The alloy should also have the ability to absorb the thermal contraction stresses due to any mismatch in expansion coefficients as well as occlusal stresses without plastic deformation. Therefore, too high of a modulus for a material with an insufficient yield strength is contraindicated, although too high of an elastic deformation is also contraindicated. High bond strengths are required so that the porcelain veneers remain attached to the alloy. The alloy system must also be chemically compatible with the porcelain. Alloying elements must not discolor porcelain yet must have tarnish and corrosion resistance to the fluids in the oral environment.

In order to promote and form high bond strengths between porcelain and alloys, the alloy must have the ability to form soluble oxides that are compatible with the porcelain. At the

firing temperature, the porcelain should spread or wet the surface of the alloy. Therefore, both mechanical and chemical interactions are involved in this process. In order to promote chemical interactions, specific oxide-forming elements, such as tin, indium, or gallium, are added to the alloy in low concentrations. The addition of iron, nickel, cobalt, copper, and zinc provide the means for hardening.

The fabrication of the PFM restoration consists of a complex set of processes. After casting, the alloy substrate is subjected to a preoxidation heat treatment to achieve the optimum surface oxides that are important for porcelain bonding. As many as three or more different porcelain firings follow. These include a thin opaque layer adjacent to the alloy, followed by body porcelain layers, including both dentin and enamel porcelain buildups. The opaque layer should mask the color of the alloy from interfering with the appearance of the porcelain. The body porcelain layers build up the restoration to the desired occlusion. The alloy-porcelain systems are slowly cooled from firing temperatures to accommodate dimensional changes occurring in both alloy and porcelain. Therefore, the alloy substrates are subjected to a number of temperature cycles during processing that affect their microstructure and properties. The slow cooling cycles also permit the formation of the compounds important for hardening of alloys.

Noble Metal PFM Alloys. The evolution of alloys for the PFM restoration has generated at least four different noble alloy systems. These are classified as gold-platinum-palladium, gold-palladium with and without silver, silver-palladium, and high-palladium content alloys (Ref 124, 147–149).

Gold-Platinum-Palladium PFM Alloys. The compositions of alloys included within this group are in the range of 80 to 90% Au, 5 to 15% Pt, 0 to 10% Pd, and 0 to 5% Ag, along with about 1% each of tin and indium. Other additions may include up to about 1% each of iron, cobalt, zinc, and copper. Platinum and palladium additions increase melting temperature and decrease thermal expansion coefficients, with platinum having the added effect of hardening the alloy. Iron is the principal hardening agent. Iron promotes the formation of an ordered iron-platinum type intermetallic phase that forms between 850 and 1050 °C (1560 and 1920 °F) on cooling from the firing temperature (Ref 124). The ordered phase is finely dispersed throughout the matrix. Iron, along with tin and indium, promotes bonding to porcelain by diffusing into the porcelain up to about 60 µm (2 mils) at the firing temperature. Tin and indium also promote solid-solution strengthening. Alloys within this group range in color from light yellow to yellow.

Even though these alloys have many advantages, their high cost and low sag resistances have necessitated the development of additional alloy systems. Unless they are used in thick sections, for example, 3×3 mm (0.12×0.12 in.),

plastic deformation of long spans will occur during firing.

Gold-Palladium and Gold-Palladium-Silver PFM Alloys. Gold-palladium with and without silver alloys were developed as alternatives to the costly gold-platinum-palladium alloys. The Au-Pd-Ag system was one of the first alternative systems. Up to 15% Ag and 30% Pd replaced all of the platinum and a large fraction of the gold from the Au-Pt-Pd system, which resulted in substantial cost savings. The gold-palladium-silver alloys possessed better mechanical properties for the PFM restoration. Because gold-palladium, gold-silver, and palladium-silver are all solid-solution alloys, the ternary Au-Pd-Ag system also forms a series of solid-solution alloys over the entire compositional ranges. Therefore, the matrices of the gold-palladium-silver dental alloys are single phase. Up to 5% Sn is added, which hardens the alloy by forming compounds with palladium that are dispersed throughout the matrix, and it serves as an oxide former and bonding agent with porcelain. Because platinum was avoided, there was no need to incorporate iron for hardening.

A major shortcoming of the Au-Pd-Ag PFM alloys was the ability of silver from the alloys to vaporize, diffuse, and combine with the porcelain at the firing temperature. This resulted in color changes, mostly greenish, along the alloy-porcelain margin, with sodium-containing porcelains being more susceptible to changes in color.

The development of the silver-free gold-palladium alloys eliminated the discoloration of the porcelain. Their compositions cover a wide range: 50 to 85% Au, 10 to 40% Pd, 0 to 5% Sn, and 0 to 5% In, along with possible additions from zinc, gallium, and other elements. The alloy matrix is based on the Au-Pd binary system, which is of the solid-solution type. Hardening is due to Pd-(In, Sn, Ga, Zn) complexes that disperse throughout the matrix. Microstructurally, a fine network of gold-rich regions are entwined by second-phase particles of Pd-(Sn, In, Ga, Zn). Their color is only a pale yellow, unlike some of the deeper yellow gold-platinum-palladium alloys. However, about a 30 to 40% cost savings is obtained. Their mechanical properties are superior, which means good sag resistance at the firing temperatures. The only disadvantage with these alloys is their lower thermal expansion coefficients when used with some of the higher-expanding porcelains.

Some gold-palladium alloys have up to 5% Ag, which is much lower than the 15% contents used with the original gold-palladium-silver alloys. The lower silver concentrations result in better thermal expansion matches with porcelain and the elimination of porcelain discoloration.

Palladium-Silver PFM Alloys. These alloys were developed out of the need to reduce the cost of the PFM restoration even more than from those fabricated from gold-palladium alloys. Compositions range from 50 to 60% Pd, 25 to

35% Ag, 5 to 10% Sn, 0 to 5% In, and up to 2% Zn.

The microstructures of the alloys are based on the Pd-Ag solid-solution system. Instead of using copper to harden the alloys, hardening occurs through compounds formed between palladium and tin, indium, zinc, and others. Hardening rates are high, which indicates non-diffusional reactions. It is likely that hardening occurs by ordering processes that form by spinodal decomposition (Ref 124). Oxides are imparted to the alloy surface because of the oxide-forming ability of indium, tin, and zinc alloying additions. This promotes high bond strengths. The mechanical properties of the palladium-silver alloys, along with the high-palladium alloys discussed subsequently, are superior to those of any other system, excluding the nickel-chromium alloys. As with the gold-palladium-silver alloys, the chief shortcoming of the palladium-silver PFM alloys is the ability of silver to discolor porcelains during firing. In order to overcome this problem, various methods have been used, including coupling agents composed of porcelains or colloidal gold.

High-Palladium PFM. The compositions of these alloys are 75 to 85% Pd with 0 to 15% Cu, 0 to 10% Ga, 0 to 8% In, 0 to 5% Co, 0 to 5% Sn, and 0 to 2% Au. The alloys are based on either the Pd-Cu-Ga or the Pd-Co-Ga ternary systems. Regardless of the high copper contents, these alloys do not induce porcelain discoloration and bonding problems. Many of these alloys have better workability than other types of PFM alloys, while retaining high hardnesses. The hardness is dependent on the formation of intermetallic compounds with palladium on cooling from the firing temperature. Because of their oxidizer content, the alloys form strong bonds with porcelain. Oxides form with palladium and the alloying additives. However, palladium oxide (PdO) forms only during heating and cooling because of the relatively low decomposition temperature for the oxide.

The oxide-forming ability of the added oxidizers is dependent on alloy composition, temperature, and time. Indium, gallium, and cobalt oxidize preferentially, while copper and tin show nonpreferential oxidation. Cobalt suppressed the oxidation for copper and tin in one alloy system (Ref 150).

Base metal PFM alloys are primarily composed of the nickel-chromium alloys. Cobalt-chromium alloys are also used, but they constitute only a very small percentage of base metal use for PFM.

The nickel-chromium PFM alloys are very similar, if not the same, as the compositions of the nickel-chromium alloys used for partial dentures, which are discussed earlier in this article. One distinction in the compositions, however, is the absence of carbon with the PFM compositions (Ref 127).

The mechanical properties of the nickel-chromium alloys are excellent for the PFM restoration. The high strengths, moduli, yield strengths, and hardnesses are used to advantage

with PFM and partial dentures. Thinner alloy sections can be made from nickel-chromium alloys than from the noble metal alloys. The flexibilities of long span partial denture frameworks are only one-half those for the high gold-content alloys. Additionally, the sag resistances of the nickel-chromium alloys at the porcelain firing temperatures are superior to all of the noble metal alloys.

The bond strengths are seriously impaired by nonadherent or loosely attached oxides. A properly attached oxide is characterized by minute protrusions on the underside of the oxide layer at the alloy/oxide interface that extends into the alloy. For alloys containing additional microstructural phases, larger peg-shaped protrusions also occur on the underside of the oxide layer, improving oxide adherence (Ref 151). The oxide layer on nickel-chromium alloys contains nickel oxide (NiO) on the exterior of the oxide scale, chromium oxide (Cr_2O_3) at the interior covering the alloy, and nickel-chromium oxide (NiCr_2O_3) in between. The relative amounts of the oxides depend on the chromium concentration and alloying elements in the alloy, as well as temperature, time of oxidation, and p_{O_2} in atmosphere.

The bond strengths between alloy and porcelain are significantly affected by minor alloying elements. The additional alloying elements of molybdenum, aluminum, silicon, boron, titanium, beryllium, and manganese also form oxides of their own. An aluminum content of 5% is necessary for aluminum oxide (Al_2O_3) to form, while 3% Si is required to form silicon dioxide (SiO_2), which increases in concentration as the alloy/oxide interface is approached. Manganese forms manganese oxide (MnO) and manganese chromite (MnCr_2O_4), and these are mainly concentrated at the outermost part of the oxide. Even though molybdenum oxide (MoO) volatilizes above 600 °C (1110 °F), molybdenum is still found in the oxide layer close to the alloy/oxide interface with alloys containing more than 3% Mo. Beryllium, which improves the adherence of the oxide layer to the alloy, is also found concentrated near the alloy/oxide interface.

The cobalt-chromium PFM alloys typically comprise nickel, tungsten, and molybdenum as major alloying elements. Tungsten and molybdenum are high-temperature strengtheners, and, therefore, increase sag resistance. Tantalum and ruthenium can also be added in minor amounts. The carbon is also reduced or eliminated with PFM alloys (Ref 127). The carbon monoxide gases generated during firing of porcelain are likely to cause porosities in the interface and in the porcelain.

Wrought Alloys for Wires

Property Requirements with Orthodontic Biomechanics. Orthodontic wires (frequently used round sizes are 0.3 to 0.7 mm, or 0.012 to 0.028 in., in diameter) constitute a large per-

centage of the wrought alloys used in dentistry. The orthodontic wires most commonly used include stainless steels, cobalt-chromium-nickel alloys, nickel-titanium alloys, and β -titanium alloys. Note that gold-base wires are used on a very limited basis (formerly, they were used more extensively). The stainless steel and cobalt-chromium-nickel wires have been used extensively with conventional orthodontic biomechanics. That is, the ability to move teeth was based to a large extent on the stiffnesses of the wire appliances. Materials with high yield strength to modulus of elasticity ratios were required. However, the nickel-titanium and β -titanium alloys take advantage of relatively lower yield strength to modulus of elasticity ratios. This is because even though slopes for the stress-strain curves of these alloys are low, the released energies (area under the stress-strain curve) can still be large, as a result of greater deflections. Certified orthodontic wires comply with the property requirements of ANSI/ADA Specification No. 32, "Orthodontic Wires," which covers base metal wires for orthodontics (Ref 152).

Stainless Steel and Cobalt-Chromium-Nickel Wires. The stainless steels used are usually the austenitic 18-8 type (approximately 18% chromium and 8% nickel by weight), although precipitation-hardening type steels have also been used. The springback of the 18-8 wires can be improved by a stress-relief heat treatment. For instance, heat treatment of the as-received drawn wires at 400 °C (750 °F) treatment for 10 min generates significant improvements in springback (Ref 153). The cobalt-chromium-nickel wires also generally include nickel and iron as other major alloying elements. Aluminum, silicon, gallium, and copper are not added to the cobalt-chromium-nickel wires, as with the PFM cobalt-chromium alloys, because bonding agents with porcelain are not needed. Mechanical properties are controlled primarily through the addition of carbon, which affects carbide formation. Although the operator has some control over the mechanical properties of the cobalt-chromium-nickel wires through heat treatments, these wires are supplied in different temper designations from soft to semiresilient to resilient (Elgiloy is one of the commonly used cobalt-chromium-nickel alloys).

Nickel-Titanium and β -Titanium Wires. The elasticity effect of nickel-titanium (generically referred to as Nitinol) is one of its most important characteristics. Nickel-titanium wires can almost be bent back on themselves without taking a permanent set. Even greater deformations, by as much as 1.6 times, can be achieved with superelastic nickel-titanium alloys (Ref 154). Nickel-titanium orthodontic alloys are primarily composed of the intermetallic compound NiTi. The alloy is tough, resilient, and has a low modulus of elasticity. Cobalt is sometimes added to nickel-titanium wires in order to obtain critical temperatures that are useful for the shape memory effect of the alloys. Furthermore, copper and chromium ranging from 5 to 6% and 0.2 to 0.5% by weight,

respectively, have been added to superelastic nickel-titanium wires to obtain shape memory at temperatures between 27 and 40 °C (81 and 104 °F); however, an in-vitro study in simulated physiologic media showed that these alloy additions did not affect the corrosion resistance of the wires (Ref 154).

Alpha-titanium (hexagonal close-packed structure) is the stable form of titanium at room temperature. By adding alloying elements to the high-temperature form of β -titanium (body-centered cubic structure), the β phase can also exist at room temperature, but in the metastable condition. The β stabilizers include molybdenum, vanadium, cobalt, tantalum, manganese, iron, chromium, nickel, cobalt, and copper. Beta-titanium is strengthened by cold working or by precipitating the phase. A variety of heat treatments can be used to alter the properties of the wires (Ref 155).

Soldering Alloys

Composition and Applications. Gold-base and silver-base solder alloys are used for the joining of separate alloy components (Table 6). High fusing temperature base alloy solders are also used for the joining of nickel-chromium and other alloys. In many cases, the term *brazing* would be more appropriate, but the term is seldom used in dentistry (technically, brazing is performed at temperatures exceeding 425 °C, or 800 °F, and soldering is performed at temperatures below this value). The gold-containing solders are used almost exclusively in bridge-work because of their superior tarnish and corrosion resistance. The use of non-noble metal containing silver-base solders is limited mainly to the joining of stainless steel and cobalt-chromium wires in orthodontic appliances because of the impermanence of the appliances.

The joining by soldering of small units to form a large one-piece partial denture is employed in some processing techniques. This is done to prevent framework distortions that may occur with large one-piece castings. The salvaging of large, poorly fitting castings by sectioning, repositioning, and soldering the pieces together also takes place. For PFM restorations, soldering is carried out either prior to or after the porcelain has been baked onto the alloy substrate. Pre-soldering uses high fusing temperature solders, while postsoldering uses lower fusing temperature solders.

Gold-base solders are most often rated according to their fineness, that is, the gold content in mass percent related to a proportional number of

Table 6 Compositions of some dental solders

Type	Composition, wt%						
	Au	Pd	Ag	Cu	Sn	In	Zn
Silver	52.6	22.2	7.1	...	14.1
Gold	45.0	...	20.6	28.4	4.3	...	2.9
Gold	63.0	2.7	19.0	8.6	...	6.5	...

units contained in 1000. Conventional gold-base crown and bridge alloys are seldom soldered together with solders having less than a 600 to 650 fineness. The soldering of gold-base wire clasps to cobalt-chromium partial dentures is another application for the higher-fineness solders. However, with the use of the low-gold-content crown and bridge alloys, lower-fineness solders are used. The lower-fineness solders are also occasionally used to solder the cobalt-chromium-nickel wires. The gold-base solders usually do not contain platinum or palladium, which increases melting temperatures. The important requirement to be satisfied during soldering is that the solders melt and flow at temperatures below the melting ranges of the parts to be joined.

The compositions of gold-base solders are largely gold-silver-copper alloys to which small amounts of other elements, such as zinc, tin, and indium, have been added to control melting temperatures and flow during melting. The silver-base solders are basically silver-copper-zinc alloys to which smaller amounts of tin have been added. The higher-fusing solders, to be used with the high-fusing alloys, are usually specially formulated for a particular alloy composition because not all alloys have good soldering characteristics.

Microstructure of Solder-Alloy Joints. The microstructural appearance of the gold alloy-solder joints provides information as to their quality. A thin, distinct, continuous demarcation between the solder alloy and the casting alloy should exist, indicating that the solder has flown freely over the surface and that no mutual diffusion between the alloys has occurred. The junction region should be free of isolated and demarcated domains, indicative of the formation of new alloy phases. Obviously, porosity is to be avoided. However, microporosity among the phases in solder may be unavoidable. As with the cooling that occurs with all alloys, differences in the thermal expansion coefficient among phases can generate microporosity. The presence of a distinct layer of columnar dendrites within the solder, starting at the solder/alloy interface and projecting into the solder bulk, is assurance that there has been no tendency of the alloy surface to melt (Ref 156). The solidified solder tends to match the grain size of the parent alloy by epitaxial nucleation of the solder by the casting alloy. The microstructural characteristics of low-gold-content casting alloys interfaced by soldering affect the microstructural characteristics of the solidified solder (Ref 156).

Microstructurally, a silver-base solder is multiphasal. Both silver- and copper-zinc-rich areas occur, which is in contrast to some of the higher-fineness gold-base solders that are single phase.

Implant Alloys

Applications and Compositions. Dental implants, which are used for supporting and attaching crowns, bridges, and partial and full

dentures, can be of the endosseous and subperiosteal types. The endosseous implants pass into or through the mandibular or maxillary arch bones, while the subperiosteal implants are positioned directly on top of or below the mandibular or maxillary bones, respectively. Endosseous implants are usually selected for size and type from implants already made, while the subperiosteal implants are usually custom made for the particular case. Therefore, both cast and wrought forms of implants are used. The alloys used for dental implants are similar in composition to the alloys mentioned previously for use with crowns and bridges and partial dentures. These include stainless steel, cobalt-chromium, and titanium and its alloys (Ref 28, 127).

Cast, Wrought, and Forged Cobalt-Chromium Alloys. In addition to castings, cobalt-chromium alloys for surgical implants

can also be obtained in the wrought and forged condition. ASTM F 1537 and F 799 for wrought and forged cobalt-chromium-molybdenum alloys, respectively, specify both low- and high-carbon alloys, along with a dispersion-strengthened alloy (Ref 157, 158). The low-carbon and dispersion-strengthened alloys have a maximum carbon content of 0.14 wt%, while the high-carbon alloy has a minimum and maximum carbon content of 0.15 and 0.35 wt%, respectively. In general, the wrought and forged cobalt-chromium-molybdenum alloys exhibit superior mechanical properties to the cast form (ASTM F 75) of the alloy.

The scanning electron micrographs in Fig. 25 show the varied microstructures of five different cobalt-chromium-molybdenum alloys (Ref 142) at the same magnification: an ASTM F 75 cast alloy, two wrought high-carbon alloys, a forged

Fig. 25 SEM micrographs in the backscattered electron mode showing the varied microstructures of five different types of cobalt-chromium-molybdenum alloys at a magnification of 1000 \times . high-carbon alloy, and a forged low-carbon alloy. The wrought high-carbon and forged high-carbon alloys have a carbon content of 0.24 wt%; the cast alloy has a carbon content of 0.22 wt%; and the forged low-carbon alloy has a carbon content of 0.05 wt%. Figures 25(b) and (c) show the wrought alloys exhibit much smaller grain sizes (about 2 to 8 μm , or 0.08 to 0.3 mils) than the cast alloy (previously described in the section "Cobalt-Chromium Alloys") and are covered by small (2 to 5 μm , or 0.08 to 0.2 mils), mostly spheroidized carbides. The wrought alloys were produced by hot-isostatic pressing powder particles and then hot rolling into a finished product. Generally, this forming operation results in a structure that has fewer voids (low porosity), greater ductility, and finer grains of greater uniformity than the original cast structure (Ref 159). The alloy in Fig. 25(c) was also aged at 730 °C (1350 °F) for 15 h. The aging of the wrought high-carbon alloy resulted in small equiaxed grains and seemed to cause the agglomeration of some of the carbides and the formation of much smaller intergranular precipitates. It is known that the aging of cobalt-chromium-molybdenum alloys produces carbide precipitation along slip lines, twin boundaries, and stacking faults upon quenching, further increasing the hardness of the alloy (Ref 160).

The single-blow forged and water-quenched, high-carbon alloy shown in Figure 25(d) also exhibits much finer grains (2 to 20 μm , or 0.08 to 0.8 mils, in size) than the cast alloy. It is covered with carbides of a semirounded morphology ranging from about 1 to 4 μm (0.04 to 0.2 mils) in size (the majority of which are located in grain boundaries) and small intergranular precipitates. In contrast, the single-blow forged and water-quenched, low-carbon alloy shown in Fig. 25(e) exhibits a highly deformed and twinned structure that contains relatively few dispersed carbides, which are less than 1 μm (0.04 mils) in size.

Modified cobalt-chromium alloys containing higher nickel contents are also used for dental implants. One wrought alloy included in this category is MP35N (35Co-35Ni-20Cr-10Mo). Microstructurally, the alloy takes the character of cobalt-chromium alloys. However, no carbides are formed because carbon has not been added to the alloy.

Porous Surfaces. Alloy powders of the same composition as the implants have been sintered onto the surfaces of the implants for generating bone ingrowth to obtain better retention between the implant and the bone.

Tarnish and Corrosion under Simulated or Accelerated Conditions

Low-Copper Amalgams. The Sn_8Hg (γ_2) phase shown in Fig. 20 is electrochemically the most active phase in conventional amalgam. Upon exposure to an electrolyte, the tin oxide (SnO)/tin couple becomes operative. The formed

SnO may or may not protect the γ_2 phase from further corrosion. Depending on environmental conditions, the tin from the γ_2 phase will either be protected by a film of SnO or consumed by additional corrosion reactions.

In the case of an artificial saliva, the γ_2 -tin becomes protected. This is shown in Fig. 26 on the anodic polarization curve as the current peak at about -0.7 V versus SCE, which relates in potential to the SnO/Sn couple. With increasing potential, the film protects the amalgam, as shown by the presence of a limiting or passivating current. The film will remain passivating until the potential of another redox reaction is reached that is controlling and nonpassivating. For instance, in a Cl^- solution, this is the situation that occurs when the corrosion potential for the amalgam approaches and surpasses the redox potential for a reaction that produces $\text{SnOCl} \cdot \text{H}_2\text{O}$.

If this condition is satisfied, the SnO passivating film is no longer thermodynamically favorable; therefore, it begins to break down and dissociate, exposing freely corroding γ_2 -tin to the electrolyte. Likewise, nonprotective products of the form $\text{SnOHCl} \cdot \text{H}_2\text{O}$ precipitate. This is represented on the polarization curve in Fig. 26 as the sharp increase in current at about -0.1 V versus SCE. As a result of the interconnection of the γ_2 phase, the interior γ_2 can also become corroded. Figure 27 shows the devastating effect that corrosion of the γ_2 phase has on the microstructure of a conventional amalgam, while Fig. 28 shows typical tin-containing products that precipitate on the surface.

High-Copper Amalgams. Corrosion of high-copper amalgams by γ_2 -phase corrosion will not occur because of its almost complete absence from the microstructure. Although possessing better corrosion resistance than the γ_2 -phase, the Cu_6Sn_5 (η') phase will be the least-resistant phase in the microstructure (Fig. 21, 22). Upon exposure to solution, any corroding tin within the material first forms a protective SnO film indicated on the anodic polarization curve in Fig. 26 as the small current peak at about -0.7 V. Upon attaining a steady-state

Fig. 26 Anodic polarization at 0.03 V/min of both low (Microalloy) and high (Sybraloy) copper amalgams in artificial saliva. Source: Ref 74

corrosion potential in chloride solution, high-copper amalgam is likely to surpass redox potentials for couples of CuCl_2/Cu , $\text{Cu}(\text{OH})_2/\text{Cu}$, $\text{Cu}_2\text{O}/\text{Cu}$, and $\text{CuCl}_2 \cdot 3\text{Cu}(\text{OH})_2/\text{Cu}$. Under these conditions, both soluble and insoluble corrosion products will form. This is indicated on the polarization curve as a small anodic current peak at about -0.25 V.

Microstructurally, if the copper from the η' phase becomes exhausted by corrosion, copper corrosion from the silver-copper and γ particles may also follow. Freed by copper corrosion, tin also becomes corroded. Corrosion of the γ_1 -tin decreases the stability of the η_1 phase, which is likely to be transformed into the β_1 phase. Unlike low-copper amalgam, the interior of high-copper amalgam, which demonstrates a lack of interconnection between any of the phases, is not likely to become affected by corrosion. Figure 29 shows a corroded high-copper dispersed-phase amalgam, emphasizing the reaction zones of the η' phase, the interior of the silver-copper particles, the γ particles, and the matrix.

Tarnish of Gold Alloys. Because tarnish is by definition the surface discoloration of a metallic material by the formation of a thin film or corrosion product, the quantification of dental alloy tarnish by assessing color changes on surfaces is most appropriate. By determining the color of an alloy before and after exposure to a test solution, the degree of discoloration can be obtained by quantitative colorimetry techniques, which are described in Ref 161 to 167. The use of quantitative colorimetry in conjunction with SIMS for determining the effects of alloy nobility (in at.%) and sulfide concentration on color changes in gold crown and bridge alloys is detailed in Ref 168.

Effect of Microstructure on Tarnishing Behavior. The devastating effect of microgalvanic coupling on tarnishing behavior is shown by a comparison of solid-solution annealed (750 °C, or 1380 °F) and as-cast structures (Fig. 30). The as-cast alloys, composed of two-phase structures, consistently showed greater color change or tarnish (Ref 164).

Single-phase, as-cast gold-silver-copper alloys with gold contents between 50 and 84 wt% were observed microstructurally to tarnish in Na₂S solutions by localized microgalvanic cells. The characteristics of the various tarnished surfaces included a uniformly speckled appearance, dendritic attack, matrix attack, grain-boundary dependent attack, and grain-boundary attack. Silver-rich areas discolored preferentially because of the operation of the silver-rich areas as anodes and the surrounding copper-rich areas as cathodes. The uniformly speckled appearance occurred with high-silver, low-copper contents, while the grain orientation dependent appearance occurred with low-silver, high-copper contents. The dendritic and matrix attack occurred with alloys containing intermediate silver and copper contents (Ref 103).

For gold-silver-copper-palladium alloys with gold contents between 35 and 73 wt%, the tarnishability in oxygenated 2% Na₂S has been shown to be affected by altering the micro-

structure through heat treatment. Tarnishing occurred on multiphase structures annealed at 500 °C (930 °F) but did not occur on single-phase structures annealed at 700 °C (1290 °F). Silver-, copper-, and palladium-rich phases were precipitated. Some alloys, though, showed only silver- and copper-rich phases. In these cases, the palladium tended to follow the copper-rich phase. Splitting of the matrix into thin lamellae of alternating silver and copper enrichments also occurred. The silver-rich phases in all materials were attacked by the sulfide and were responsible for the tarnish. Age hardening by AuCu(I)-ordered precipitates increased the tendency of the silver-rich lamellae to tarnish (Ref 169).

In sulfide solutions, silver sulfide (Ag₂S) is the principle product of tarnish, although copper sulfides (Cu₂S and CuS) also form. These products are produced by the operation of microgalvanic cells set up between silver-rich and copper-rich lamellae. The addition of palladium to gold-silver-copper alloys considerably reduces the rate of tarnishing by slowing down the formation of a layer of silver and copper sulfides on the surface. This has been shown to be due to the enrichment of palladium and gold on the surface of the alloy when exposed to the atmosphere prior to sulfide exposure (Ref 170). The rate of diffusion from the bulk to the surface is hindered by the palladium enrichment. The active sites on the alloy surface for the sulfidation reaction are selectively blocked by the palladium atoms (Ref 170).

Effect of the Silver/Copper Ratio. The silver/copper ratio is an important aspect affecting the tarnish and corrosion resistance of gold dental alloys. A comparison was made of three gold alloys, with similar noble metal

contents, but different Ag/Cu ratios (based on wt%) of 41/7.4, 10.3/37.9, and 9.8/37.7 (Ref 169). Polarization tests of the three alloys in a sulfide solution showed that the alloy with a Ag/Cu ratio of 41/7.4 exhibited increases in current density up to 10 µA/cm² at -0.3 V, while the other two alloys exhibited current densities of ~1 µA/cm² extending to positive potentials. Therefore, high silver contents relative to low copper contents in low-gold alloys can have detrimental effects on tarnishing and corrosion. For some low-gold alloys, the best resistance to tarnishing has been obtained by using Ag/Co ratios between 1.2 and 1.4 and a palladium content of 9 wt%.

Effect of the Palladium/Gold Ratio. Increasing the palladium content in gold alloys increases the tarnish resistance. However, in gold-silver-copper-palladium alloys, this effect is greater. The palladium/gold ratio is just as important as the silver/copper ratio. In gold-silver-copper alloys without palladium, the degree of tarnish (subjective test: 0 = least and 8 = most) was evaluated to be between 6.5 and 8 for all silver/copper ratios (1:3, 1:2, 2:3, 1:1, 3:2, 2:1, 3:1) (Ref 108). However, in alloys having palladium/gold ratios of 1:12, the degree of tarnish diminished to between 2 and 3.

Tarnishing and Corrosion Compared.

Figure 31 shows reflection loss versus nobility and mass loss versus nobility for 15 gold alloys. Tarnishing was by immersion for 3 days in 0.1 mol/L Na₂S, while corrosion was by immersion for seven days in aerated 0.1 mol/L lactic acid plus 0.1 mol/L NaCl at 37 °C. As is evident, a number of alloys that appear not to have been affected by corrosion are, however, largely affected by tarnishing (Ref 171).

Corrosion of Gold Alloys. Electrochemical polarization has been applied to the corrosion evaluation of gold dental alloys. Very small current peaks on the anodic polarization curves for some gold alloys in artificial saliva have been detected and interpreted to be due to the dissolution of alloying components (Ref 172).

A comparison of the anodic polarization of noble alloys in artificial saliva with and without sulfide indicated that without sulfide the electrochemistry is governed mainly by chloride ions. The alloys passivate in a state with very low current densities, which makes detection of differences among the alloys difficult. With sulfide added to the artificial saliva, a preferential sulfidation of the less noble alloy component is induced. The sulfidation is characterized by a critical potential and limiting current density, both of which may be dependent on composition (Ref 173).

The corrosion susceptibilities for silver and copper in various gold alloys were quantified by an analysis of both forward and reverse polarization scans (Ref 174). Both silver and copper demonstrated characteristic current peaks. The heights of the current peaks were taken to be a measure of the amount of corrodible silver and copper in the alloys. In a similar technique, the

Fig. 29 SEM micrograph of corroded (5 µA/cm²/d) high-copper amalgam (cluster) in 0.2% NaCl solution. Note the definition of the γ' rings (A), Ag-Cu particles (B), matrix (C), and η' particles (D).

Fig. 30 Color change vector ΔE^* for three low-gold alloys (I, Miracast; II, Sunrise; III, Tiffany) in both the as-cast (left bar for each alloy) and solutionized at 750 °C (1380 °F) (right bar for each alloy) conditions after exposure for 3 days to artificial saliva (A) or 0.5% Na₂S solution (B). Source: Ref 164

integrated current from the polarization curves within a potential range of -0.3 V to $+0.3$ V versus SCE was taken to be a measure for the corrodible species (Ref 175). Figure 32 shows a plot of the nobility of eight as-cast gold alloys versus their integrated anodic currents.

Silver-Palladium Alloys. Silver is prone to tarnishing by sulfur and is prone to corrosion by chloride. The addition of palladium to silver generates alloys with much better resistance to tarnishing and silver corrosion. In 1/7 diluted Ringer's solution and 0.1% NaCl, alloys with more than 40% Pd showed passive anodic polarization behavior (Ref 176). In sulfur-saturated air, the amount of sulfur deposited onto the surfaces of silver-palladium alloys was minimal for compositions with ≥ 40 wt% Pd (Ref 173). In artificial saliva, two transitions in the corrosion currents occurred with palladium content. The first occurred at about 22% Pd, where the current decreased from 6 to $1 \mu\text{A}$. The second transition occurred at about 29% Pd, where the current decreased to about $0.4 \mu\text{A}$ and then remained fairly constant throughout the rest of the compositional range (Ref 177). Figure 33 shows the color range vectors for the pure metals and alloys from the Ag-Pd system after tarnishing in artificial saliva with 0.5% Na_2S . The compositions 50Pd-50Ag and 75Pd-25Ag showed the best tarnish resistance (Ref 178).

Corrosion behavior and tarnishing behavior usually must be viewed independently. That is, corrosion is not an indicator for tarnishing, and vice versa. Alloy nobility dominates corrosion behavior, while alloy nobility, composition, and microstructure (in conjunction with environment) influence tarnishing behavior.

Microstructurally, the silver-palladium alloys tarnish by chlorides and/or sulfides becoming deposited over the silver-rich matrix, while the palladium-rich precipitates display resistance to chlorides and sulfides. Furthermore, microstructurally, the alloys are generally composed of a corrosion-resistant copper- and palladium-rich phase and a nonresistant silver-rich phase. Increased tarnish and corrosion of this silver-rich phase component can occur as a result of microgalvanic coupling (Ref 179). Manipulation of the microstructural features through heat treatments can produce structures with varying proportions of the tarnish-resistant and tarnish-prone phases. For example, age hardening has been shown to increase the proportion of the tarnish- and corrosion-prone phases (Ref 180, 181).

High-Palladium PFM Alloys. Alloys with up to 80 wt% Pd and additions of copper, gallium, tin, indium, gold, and others have been shown to exhibit good saline corrosion resistance in the potential range and Cl^- ion concentration associated with oral use. For example, anodic polarization tests showed passive behavior until breakdown occurred, which was at potential magnitudes well above those occurring intra-orally (Ref 182).

Nickel-Chromium Alloys. The tarnish resistance and corrosion resistance of these alloys result from balancing the composition with regard to the passivating elements chromium, molybdenum, manganese, and silicon. Alloys containing increased amounts of molybdenum and manganese have shown to exhibit increased passivation; however, increasing the chromium content too much (more than 20%)

can precipitate an additional phase and alter the corrosion resistance. By using polarization methods, three different behaviors were observed with 12 nickel-chromium alloys with varying compositions in deaerated and aerated artificial saliva (Ref 183). Some alloys were constantly passive, others were either active/passive or passive according to the aeration condition of the electrolyte, and still others ($<16\%$ Cr without molybdenum) were constantly active and corroding.

Corrosion potentials for nickel-chromium alloys in artificial saliva were low, ranging between about -0.2 V and -0.8 V versus SCE. Breakdown potentials varied, depending on composition. For alloys with less than 16% Cr and no molybdenum, breakdown potentials as low as -0.2 V occurred. For compositions with higher chromium contents and with molybdenum and various manganese contents, breakdown potentials as high as $+0.6$ V also occurred.

Pitting attack occurs with these alloys because they rely on protective surface oxide films for

Fig. 31 Effect of nobility (in atomic percent) on tarnish (percent loss in reflection after 3 days in 0.1% Na_2S) and corrosion (mass loss after 7 days in aerated 0.1 mol/L lactic acid plus 0.1 mol/L NaCl at 37°C , or 99°F) of 15 gold alloys. Source: Ref 171

Fig. 32 Integrated anodic currents between -0.3 V vs. saturated calomel electrode (SCE) and $+0.3$ V (at 0.06 V/min) for eight gold alloys in deaerated 1% NaCl plotted against the atomic nobility. Source: Ref 164

imparting protection. From electrochemical and immersion tests, the resistance of nickel-chromium alloys to pitting attack was found to be good in solutions with Cl^- concentrations equivalent to that found in saliva. Only at higher Cl^- concentrations are pitting and tarnishing likely to occur (Ref 184).

Cobalt-Chromium Alloys. Compared with the nickel-chromium alloys, the cobalt-chromium alloys for partial denture and implant prosthesis exhibit superior tarnish and corrosion resistance. Figure 34 shows the polarization curve for the cast cobalt-chromium-molybdenum alloy shown in Fig. 25(a). The alloy was tested at a scan rate of approximately 1.5 mV/s (1.8 V/h) in aerated physiologic phosphate buffered saline (PBS) that was heated and held at a temperature of $37 \pm 1^\circ\text{C}$ ($99 \pm 2^\circ\text{F}$) with a pH of 7.4 ± 0.2 (Ref 142, 185). From this curve, the breakdown potential (E_b), protection potential (E_p), zero current potential (E_{zcp}), and passive current density (J_p) can be determined. Table 7 lists the mean values of these parameters for the five different types of cobalt-chromium-molybdenum alloys shown in Fig. 25. A one-way analysis of variance test revealed no statistical differences between the groups for any of the parameters listed in Table 7 at the p (probability of occurrence) < 0.05 level.

In Fig. 34, the potential at which the up and down scans intersect is the protection potential, E_p . Below this potential, existing pits will not grow (Ref 186). The magnitude of the hysteresis between the up and down scans is $E_b - E_p$, which is considered to be a measure of the degree of pitting (Ref 134, 186, 187). Thus, $E_b - E_p$ is used to characterize the susceptibility of an alloy to pitting or crevice corrosion. Consequently, from Table 7, it can be seen that the different cobalt-

chromium-molybdenum alloys did not show a significant difference in their susceptibility to pitting or crevice corrosion.

Table 7 also lists the results of impedance spectroscopy tests performed on the five different types of cobalt-chromium-molybdenum alloys shown in Fig. 25 (Ref 142, 185). The test solution and conditions were the same as for the polarization tests described previously. Impedance spectrums were collected every 50 mV, starting at -1000 mV, up to $+700$ mV, and back down to -1000 mV versus Ag/AgCl, for a total of 68 impedance spectrums. The average maximum early resistance (R_e) and polarization resistance (R_p) values for each alloy group are displayed in Table 7, along with the average minimum capacitance (C) values (note that analysis of the impedance values indicated that the R_p values were controlled by the rate of the corrosion process, as opposed to being controlled by charge transfer resistance, and the R_e values were a combination of the solution resistance and the oxide film resistance). One-way analysis of variance tests were performed on the impedance values in Table 7 and the results did not indicate any significant differences between the alloy groups for any of the parameters at the $p < 0.05$ level. Thus, the similar passive electrochemical behavior of the five different cobalt-chromium-molybdenum alloy groups, as shown by the results of the impedance and polarization tests in Table 7, suggests that the oxide films covering them were not significantly altered by changes in carbon content and processing.

However, studies have shown that carbide content and grain size are both factors that may affect the corrosion resistance of cobalt-chromium-molybdenum alloys. For instance, Placko et al. investigated cobalt-chromium-molybdenum alloy porous coatings with four different microstructures (Ref 188). They observed that, for accelerated anodic corrosion experiments, an increase in carbide content correlated with an increase in severity of the

preferential attack of the areas surrounding carbides, which was most likely attributable to the phenomenon of sensitization (a depletion of the chromium in the material matrix surrounding carbides). Furthermore, it was also noted that as grain size decreased for the microstructures, localized attack of the grain boundaries increased.

On the other hand, research by Devine and Wulff found that the crevice corrosion resistance for cast cobalt-chromium-molybdenum alloy was not as great as for the wrought material (Ref 189). They ascribed this finding to the greater chemical homogeneity of the wrought cobalt-chromium-molybdenum alloy, as determined by electron microprobe measurements. Also, optical micrographs comparing the cast with the wrought material showed the wrought material to possess a finer grain size and a more uniform and finer distribution of carbides.

In spite of the excellent corrosion resistance of cobalt-chromium alloys, allergic reactions to cobalt, chromium, and nickel contained in appliances made from these alloys are known to have occurred (see the section "Allergic Hypersensitive Reactions" in this article).

Titanium Alloys. The anodic polarization for pure titanium and its alloys indicates passivities over at least several volts in overvoltage (Ref 77, 190). This demonstrates the tenacity and protectiveness of the titanium oxide films formed on these materials.

With regard to the casting titanium alloys for crown and bridgework and partial dentures, good corrosion resistance is still preserved (Ref 191). However, a point of concern is the higher percentages of alloying elements in the titanium casting alloys, with the potential for elucidating diminished chemical stabilities.

Wrought Orthodontic Wires. A comparison of their anodic polarization curves (Fig. 35) shows that both β -titanium and cobalt-chromium-nickel (Elgiloy) exhibit resistance to corrosion in artificial saliva, within the

Fig. 34 Polarization curve for cast cobalt-chromium-molybdenum alloy shown in Fig. 25(a). The alloy was tested at a scan rate of about 1.5 mV/s (1.8 V/h) in aerated physiologic phosphate buffered saline (PBS) that was heated and held at a temperature of $37 \pm 1^\circ\text{C}$ ($99 \pm 2^\circ\text{F}$) with a pH of 7.4 ± 0.2 . The sample was scanned from -1000 to $+700$ mV vs. Ag/AgCl and back down to -1000 mV vs. Ag/AgCl. Source: Ref 142

Table 7 Polarization and impedance data for five different cobalt-chromium-molybdenum alloys shown in Fig. 25 and described in the section "Cost, Wrought, and Forged Cobalt-Chromium Alloys"

Property	Alloy				
	Cast	WHC	WHCA	FHC	FLC
Polarization data(a)(b)

Source: Ref 142

potential ranges employed (+0.8 V vs. SCE) in the study. With the nickel-titanium and stainless steel wires, breakdown occurred at +0.2 and 0.05 V versus SCE, respectively. The nickel-titanium and stainless steel wires also exhibited current increases upon potential reversals at +0.8 V versus SCE, an indication of their susceptibility to pitting corrosion. Breakdown potentials differed by as much as 0.6 V between different brands of stainless steel wires. Variations in the polarization characteristics of stainless steel have been related to microstructure (Ref 77) and to surface preparation and finish (Ref 78). It has been shown that the resistance to pitting is decreased with increasing cold deformation for stainless steel in a NaCl solution; the pitting potential decreased by over 300 mV as the degree of cold deformation increased from 0 to 50% (Ref 193). Microstructurally, nickel-titanium wires have been observed to suffer pitting attack and selective dissolution of nickel after polarization tests (Ref 193). Furthermore, it has been shown that the dissolution of nickel can take place at sites of surface damage on nickel-titanium wires, which can be a concern to nickel-sensitive patients (Ref 154).

Fig. 35 Anodic polarization at 0.03 V/min of four orthodontic wires in artificial saliva. Source: Ref 192

Fig. 38 Anodic polarization at 0.03 V/min of silver and gold (450 fine) solders in 1% NaCl solution. Source: Ref 194

Silver and Gold Solders. A corroded stainless steel-silver soldered joint is shown in Fig. 36. Microstructurally, silver solders are composed of two phases: silver- and copper-zinc rich segregations (Ref 194). The copper-zinc regions are the least resistant to corrosion. These solders corrode by microgalvanic coupling, either by cells set up between the two microstructural phases, or between the solder and the parts they join. Figure 37 shows the copper-zinc phase of a silver solder attacked by corrosion.

Figure 38 shows the polarization curves for both silver and gold (450 fine) solders in 0.16 M NaCl. The silver solder demonstrates active behavior. Zinc, tin, copper, and even silver products can be precipitated or become dissolved in solution. The polarization curve for gold solder indicates activity by the sharp current density peak at +0.25 V versus SCE. Because the solder contains silver, copper, and zinc, in addition to gold, this peak is probably due to the corrosion of one of these elements. Figure 39 shows the gold solder after the polarization test. Corrosion has delineated the basic microstructure of the solder alloy.

Fig. 39 SEM micrograph of a corroded (polarized to +0.5 V vs. SCE) gold solder (450 solder) in 1% NaCl. The light areas contain chlorine. Source: Ref 194

Chlorine was detected with the white appearing phase.

Silver-Indium Alloys. These alloys rely on the unusual properties of indium oxide for providing tarnish and corrosion control. Small amounts of noble metals, such as palladium, may also be added in an attempt to improve corrosion resistance. Anodic polarization of a silver-indium alloy in artificial saliva indicated only a very narrow potential range of about 0.1 V of reduced current densities. The tarnish resistance of these alloys appears to be acceptable, but the long-term corrosion resistance has yet to be established (Ref 195).

Copper-Aluminum Alloys. A comparison of the released copper in human saliva from a dental copper-aluminum alloy to that from a high-copper amalgam is shown in Fig. 40. The amalgam released more copper over a 45 day interval. No aluminum, iron, manganese, or nickel was detected. Figures 41(a) to (c) show micrographs from an in vivo restoration of various magnifications. Large amounts of organic matter were adsorbed onto the surface, as well as light powdery corrosion products composed of copper oxides.

Corrosion in Petroleum Production Operations

Revised by Russell D. Kane, Honeywell Process Solutions, Honeywell International, Inc.

THE PRODUCTION of oil and gas, its transportation and refining, and its subsequent use as fuel and raw materials for chemicals constitute a complex and demanding process where corrosion (in all its many forms) is an inherent hazard. The costs in terms of lost production, the replacement of materials of construction, and the constant personnel involvement in corrosion control are substantial. If not controlled, corrosion can result in leaks and catastrophic failures that can lead to additional expenses related to environmental hazards, equipment wastage, injury, and loss of life.

The total cost of corrosion in the U.S. oil and gas production industry is estimated to be \$1.372 billion annually, made up from \$589 million for surface piping and facility costs, \$463 million in downhole tubing expenses, and \$320 million in capital expenditures related to corrosion (see the article "Direct Costs of Corrosion in the United States" in *Corrosion*, Volume 13A, of the *ASM Handbook*). The control of corrosion through the use of coatings, metallurgy, nonmetallic materials of construction, cathodic protection, inhibitors, and other methods has evolved into a science in its own right and has created industries devoted solely to corrosion control in specific areas.

This article discusses the particular corrosion problems encountered and the methods of control used in petroleum production (i.e., upstream) and the storage and transportation of oil and gas (i.e., midstream) up to the refinery (i.e., downstream). Refinery corrosion is discussed in the article "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume.

Although industry standards and specification are referenced throughout this article, additional information can also be found in the article "Corrosion in Petroleum Refining and Petrochemical Operations" which lists U.S. and international standards for both petroleum production and refining operations (refer to the Appendix "Industry Standards").

Causes of Corrosion

This section concentrates on those aspects of corrosion that tend to be unique to corrosion as encountered in applications involving oil and gas exploration and production, namely extracting oil and gas from underground reservoirs and sending these products through a gathering system of pipelines to processing facilities.

The most unique and hostile environments are commonly found in actual production formations (i.e., downhole oil and gas reservoirs), which, in the absence of contamination, are devoid of oxygen. In situ corrosives normally include carbon dioxide (CO₂), hydrogen sulfide (H₂S), polysulfides, organic acids, and elemental sulfur. In certain circumstances, natural gas reservoirs may also contain elemental mercury as an additional impurity with the result being additional concerns from the standpoint of corrosion (these are discussed in the articles on "Liquid Metal Corrosion" and "Liquid Metal Induced Embrittlement" in Volume 13A of the *ASM Handbook*). Additional unique aspects are the extremes of temperature and, particularly, pressure encountered. In deep gas wells (6000 m, or 20,000 ft), temperatures approaching 230 °C (450 °F) have been present, and partial pressures of CO₂ and H₂S of the order of 20.7 MPa (3000 psi) and 48 MPa (7000 psi), respectively, have been encountered. Total system pressures can commonly reach levels between 34.5 and 138 MPa (5000 and 20,000 psi). Additionally, oil and gas production from reservoirs under deep ocean waters must enter submarine production pipelines and related equipment. The production environment is quickly cooled from the high temperatures mentioned previously to near freezing temperatures (1 to 4 °C, or 35 to 40 °F) by the surrounding deep sea environment. This condition can involve precipitation of additional liquid water in the environment to contribute to corro-

sivity. Additionally, production pipelines and equipment in arctic regions routinely is designed to operate at -40 to -50 °C (-40 to -60 °F).

Convenient access to the most important literature on H₂S corrosion (particularly with regard to sulfide stress cracking, SSC; hydrogen induced cracking, HIC; and the related problem of stress oriented hydrogen induced cracking, SOHIC) and CO₂ corrosion is available in Ref 1 to 14.

The initially oxygen-free geologic environment may be altered by a variety of oxygen-contaminated fluids that can be introduced. Examples are drilling fluids (often referred to as "muds"), which are used during drilling and maintenance of wells. These can include high-density clear brines such as calcium chloride (CaCl₂), calcium bromide (CaBr₂), and zinc bromide (ZnBr₂); various aqueous solutions including seawater or reinjected water separated from oil and gas production; alternating water, steam and/or CO₂ injected for secondary oil recovery; and strong inorganic and organic acids (e.g., hydrochloric, HCl, hydrofluoric, HF, formic, HCOOH, and others) that are injected down the well and into the formation to increase formation permeability for better flow of hydrocarbons. Some of these fluids are inherently corrosive; others are potentially corrosive only when contaminated with oxygen, CO₂, and/or H₂S, and some can become thermally unstable and liberate corrosive species in situ. Particularly damaging in these situations is the fact that corrosion is likely to be localized leading to pitting, local area attack, crevice corrosion, and/or stress-corrosion cracking (SCC) (Ref 15).

Oxygen is also responsible for the external corrosion of offshore platforms and drilling rigs. In oil and gas production, highly stressed structural members are directly exposed to a corrosive, aerated seawater environment. This also makes localized corrosion and corrosion fatigue a particular concern. Additionally, SCC can occur in stainless steel topside piping and equipment, if not properly selected for this harsh environment.

Another unique aspect of oil and gas production operations, particularly in older fields, is the almost exclusive use of carbon and low-alloy steels. More recently, there has been extensive use of corrosion-resistant alloys. These materials include martensitic, austenitic, and duplex stainless steels, nickel-base alloys, and titanium alloys. They have been typically justified by the reduction in costs associated with operations, replacement, maintenance, and/or more conventional corrosion inhibition of steel. These more corrosion-resistant alloys have been utilized most extensively in remote and/or offshore operations where costs related to corrosion and its control are typically higher than for more conventional onshore oil-field applications. As wells are being drilled deeper, higher formation pressures are encountered, and as offshore wells are located in deeper waters, the emphasis is increasingly on both corrosion resistance and higher strength to improve load-carrying capabilities. The relevant concern is that higher-strength materials often exhibit greater sensitivities to environmentally assisted cracking, EAC (e.g., SCC and hydrogen embrittlement cracking, HEC). Therefore, these materials often require special developments in alloy composition and/or metallurgical processing to provide for increased resistance to EAC at levels of applied stress to make them viable for constantly more challenging applications in the quest for oil and gas.

Oxygen

Although it is not normally present in rock formations at depths more than approximately 100 m (330 ft) below the surface of the earth, gaseous oxygen (O_2)—or oxygen dissolved in aqueous media—is nevertheless responsible for a great deal of the corrosion encountered in oil and gas exploration and production. However, oxygen-induced internal corrosion problems tend to be greater in applications where much of the processing and handling occurs at or near the surface at near-ambient pressure. This makes oxygen contamination through leaking pump seals, casing and process vents, open hatches, open handling (as in mud pits during drilling, trucking, and so on), and in seawater-injection systems highly likely. Also, failure of oxygen-removal processes (gas stripping and chemical scavenging) is a relatively common occurrence in water-injection systems (see the discussion “Corrosion in Secondary Recovery Operations” in this article).

A number of the properties of oxygen contribute to its uniqueness as a corrosive. Oxygen almost by definition is a strong oxidant. This means that even trace concentrations (≥ 10 ppb) can be harmful, to a varying degree, depending on its concentration and other corrosive constituents in the system. The corrosion potential of steel under these conditions (almost 1.3 V) is high enough to overcome very substantial

potential drops between anodic and cathodic sites. Also, the kinetics of oxygen reduction on a metal or conductive oxide surface are relatively fast. This, coupled with the low solubility of oxygen in water and brines, tends to produce conditions in which the mass transport of oxygen is the rate-limiting step in the corrosion of carbon and low-alloy steels in nonacidic environments.

Mass transport is important in a number of aspects of oxygen corrosion and corrosion control. On newly installed bare steel offshore structures, mass transport of oxygen governs electrical current requirements for cathodic protection in seawater. Once a calcareous deposit forms on cathodically protected steel, the current demand to maintain cathodic protection is reduced considerably. However, poor mass transport under deposits and in crevices promotes localization of attack particularly if deposits are nonuniform. In the final analysis, limiting the mass transport of oxygen plays a critical role in much of the corrosion control in oxygenated systems.

The crucial role of mass transport can be illustrated as follows. At ambient conditions, water equilibrated with air will contain about 5 to 8 ppm of oxygen depending on specific conditions and the presence of dissolved salts. Under such conditions, mass-transport limited rates of general corrosion of steel range from about 0.25 mm/yr (10 mils/yr) in a stagnant system to 15 mm/yr (600 mils/yr) in a highly turbulent one. However, by chemically scavenging the oxygen concentration down to the order of <10 ppb, the corresponding rates are reduced to less than about 0.01 mm/yr (0.4 mils/yr). Such rates are acceptable. Under these conditions, magnetite forms as a stable protective corrosion product film and further lowers the corrosion rate by introducing a slower, anodically controlling step.

An even more fundamental role of magnetite should be acknowledged. This is its role as a protective barrier on the steel surface that limits the reaction of steel with water or the hydrogen ions contained in the water. Therefore, if an excess of a chelating agent such as ethylenediamine tetraacetic acid (EDTA) dissolves a protective magnetite film, as could occur in regions of high turbulence, rapid corrosion ensues, despite the absence of oxygen.

The interrelationship of oxygen concentration, flow rate, and temperature in seawater-handling systems is shown in Fig. 1 (Ref 16).

Hydrogen Sulfide, Polysulfides, and Sulfur

Hydrogen sulfide, when dissolved in water, is a weak acid and is therefore corrosive because it is a source of hydrogen ions. In the absence of buffering ions, water equilibrated with 1 atm of H_2S or CO_2 (often referred to as acid gases) has a pH of about 4. However, under conditions

of high-pressure hydrocarbon formations, pH values as low as 3 have been observed. In some cases, buffering species in produced water (such as bicarbonate) can result in higher pH values than expected based on just the amount of acid gases present. This can have a direct mitigating effect on corrosion rate and, in some cases, promote the formation of protective corrosion films, thus reducing the corrosion rate to very low levels.

Hydrogen sulfide can also play other roles in corrosion in oil and gas production. The sulfur on the metal surface resulting from the H_2S corrosion reaction readily acts as a catalyst to promote absorption of atomic hydrogen into the corroding steel. Atomic hydrogen—also referred to as nascent hydrogen (H^0)—is formed by the cathodic reduction of hydrogen ions. This accounts for its role in promoting SSC, HIC, and SOHIC in steels. Stress-corrosion cracking is usually found in steel with a yield strength greater than approximately 550 MPa (80 ksi), whereas HIC and SOHIC are found in low-strength steels less than 550 MPa (80 ksi) (Ref 3).

Hydrogen sulfide also reacts with elemental sulfur. In a gas phase with a high H_2S partial pressure, sulfanes (free-acid forms of a polysulfide) are formed so that elemental sulfur is rendered mobile and is produced along with the remaining gaseous constituents. However, as the pressure decreases traveling up the production tubing, the sulfanes dissociate and elemental sulfur precipitates. Production environments with H_2S and sulfur have been found to be more severe from the corrosion and EAC standpoint than environments with H_2S alone. Various solvent treatments are used to avoid plugging by such sulfur, but their effect on corrosion and EAC need also to be considered during evaluation.

In the aqueous phase, under acidic conditions, sulfanes are also largely dissociated into H_2S and elemental sulfur. However, enough strongly oxidizing species can remain either as polysulfide ions or as traces of sulfanes to play a significant

Fig. 1 Effect of flow rate, temperature, and oxygen on corrosion rate of steel in saltwater. Source: Ref 16

role in corrosion reactions. Oxygen contamination of sour (H_2S -containing) systems can also result in the formation of polysulfide and/or the precipitation of elemental sulfur generally leading to an increase in corrosivity.

Iron sulfide corrosion products can be important in corrosion control. Because of the low solubility, rapid precipitation, and mechanical properties of such corrosion products, velocity effects are not as commonly encountered in sour (H_2S -containing) systems as in sweet (CO_2 -containing) systems. However, this effect can also be influenced by the morphology and actual crystalline form of iron sulfide, which can depend on temperature and H_2S concentration, among other factors.

The great range of possible iron sulfide corrosion products and their possible effects on corrosion have been extensively studied (Ref 17–23). This continues to be an area of interest in corrosion control and prediction. At lower temperatures and very low H_2S partial pressures, a somewhat protective sulfide film often forms. The absence of chloride salts strongly promotes this condition, and the absence of oxygen is absolutely essential. Under these conditions, the formation of a sulfide film often results in a remarkable decrease in corrosion rate when compared to similar conditions (CO_2 only) without H_2S .

At the high temperatures (150 to 230 °C, or 300 to 450 °F) and H_2S partial pressures (hundreds to thousands of pounds per square inch) encountered in deep sour gas wells, a so-called barnacle type of localized corrosion (Ref 21) can occur, resulting in corrosion rates of several hundred mils per year (Ref 22). This type of attack is strongly promoted by sulfidic species and requires the presence of some minimum chloride concentration. Although initially recognized in deep sour well environments, this same mechanism may operate at lower temperature in pipelines where high levels of H_2S and high chloride concentrations are observed.

In the barnacle mechanism (Fig. 2), corrosion can be sustained beneath thick but porous iron sulfide deposits (primarily pyrrhotite, $\text{FeS}_{1.15}$) because the FeS surface is an effective cathode. The anodic reaction beneath the FeS deposit is dependent on the presence of a thin layer of concentrated iron chloride (FeCl_2) at the Fe/FeS interface. This intervening FeCl_2 layer is acidic due to ferrous ion hydrolysis, thus preventing precipitation of FeS directly on the corroding steel surface and enabling the anodic reaction to be sustained by the cathodic reaction on the external FeS surface.

Carbon Dioxide

Carbon dioxide, like H_2S , is a weakly acidic gas (often referred to as an acid gas) and becomes corrosive when dissolved in water. However, CO_2 must first hydrate to form carbonic acid (H_2CO_3)—a relatively slow reaction—before it

is acidic. There are other marked differences between the two systems. Velocity effects are very important in the CO_2 system; corrosion rates can reach very high levels approaching 12.5 to 37.5 mm/yr (500 to 1500 mils/yr), and the presence of salts is often unimportant.

Whether or not corrosion in a CO_2 system is inherently controlled or uncontrolled depends critically on the factors governing the deposition and retention of a protective iron carbonate (siderite) scale. On the other hand, there are the factors that determine the rate of corrosion on bare steel. These latter factors govern the importance of maintaining corrosion control.

For simple systems, bare steel (worst case) corrosion rates can be estimated from Eq 1, which was developed on the basis of electrochemical studies of the aqueous CO_2 /carbon steel system (Ref 24):

$$\text{Log } R = A - \frac{2320}{t + 273} - \frac{5.55t}{1000} + 0.67 \log \bar{p} \quad (\text{Eq 1})$$

where R is the corrosion rate, t is temperature (°C), A is a constant, and \bar{p} is CO_2 partial pressure. When R is calculated in millimeters per year and \bar{p} is in atmospheres, $A = 7.96$. When R is calculated in mils per year and \bar{p} is in pounds per square inch, $A = 8.78$.

Corrosion rates calculated with Eq 1 reach 25 mm/yr (1000 mils/yr) at 65 °C (150 °F) and 1 MPa (150 psi) CO_2 pressure, and 250 mm/yr (10,000 mils/yr) at 82 °C (180 °F) and 16 MPa (2300 psi) CO_2 pressure. Obviously, such rates are unacceptable. An alternative, idealized condition occurs when a protective carbonate scale is present and when the corrosion rate is limited by the need to replenish the film lost due to solubility in the aqueous phase. Under such conditions, the rates calculated for a hypothetical

sweet (CO_2 -containing) gas well reached a maximum of about 0.15 mm/yr (6 mils/yr) as compared to calculated bare metal rates of 500 to 2000 mm/yr (20,000 to 80,000 mils/yr) (Ref 25).

Conditions favoring the formation of a protective iron carbonate scale are:

- Elevated temperatures greater than 60 °C (140 °F) (decreased scale solubility, decreased CO_2 solubility, and accelerated precipitation kinetics)
- Increased pH above 4.0, as occurs in bicarbonate-containing waters (decreased solubility) or in conditions of iron supersaturation from buildup of iron corrosion products in the aqueous phase
- Lack of turbulence—low wall shear stress conditions provide minimal mechanical forces that can disrupt normally protective (pseudo-passive) surface films on the metal surface

Turbulence is often the critical factor in pushing a sweet system into a corrosive regime. Excessive degrees of turbulence prevent either the formation or retention of a protective iron carbonate film.

A critical velocity equation has been used to estimate when excessive turbulence can be expected in a CO_2 system (Ref 26). There is no doubt that the velocity effect is real, but it is accepted that the following equation is an oversimplification:

$$\text{Critical velocity} = \frac{K}{\sqrt{\rho}} \quad (\text{Eq 2})$$

where velocity is calculated in feet per second, K is a constant, and ρ is the density of the produced fluid (liquid + gas combined). When ρ is in kilograms per cubic meter, $K = 7.6$; for ρ in pounds per cubic foot, $K = 100$. More commonly today, rigorous multiphase flow modeling is conducted using software tools that can assess production rates for water, oil, and gas to determine the applicable flow regime (e.g., stratified, slug, mist, etc.) and the magnitude of the wall shear stress present from the flow in addition to local turbulence from geometric considerations (e.g., surface roughness, weld protrusion, bends, tees, etc.) as well as gravitational forces that influence multiphase flow (i.e., horizontal, upward, and downward flow). Table 1 shows the impact of various multiphase flow parameters on the flow behavior and resultant wall shear stresses produced. It can be seen that it is not always the highest flow velocity that produces the most severe condition; it is more related to local turbulence, flow-induced turbulence (i.e., slug flow), and the physical parameters of the flowing media (Ref 25, 26, 28).

Currently, state-of-the-art in corrosion assessment utilizes predictive software tools that can facilitate the use of many simultaneous parametric effects on corrosion through input of production variables (see Fig. 3). Such software tools often incorporate various theoretical and mathematical models combined with heuristics

Fig. 2 Barnacle mechanism of sour pitting corrosion. Source: Ref 22

to adjust the calculated corrosion rates based on actual field/plant experience and the results of empirical studies. The most sophisticated models also have the ability to:

- Determine the effects of pH (taking into account CO_2 , H_2S , bicarbonate, acetate, and iron supersaturation in the environment) on corrosion scale formation

Table 1 Typical local liquid wall shear stress values determined by modeling for various multiphase flow regimes

Internal pipe wall condition	Flow conditions at pipe wall and corresponding shear stress, Pa			
	Stratified smooth	Slug		Annular wavy
Straight pipe	3	Moderate	Extreme	10
Pipe with pitting	5	100	200	15
3D-bend	5	150	300	15
5 mm (0.2 in.) weld bead	10	150	300	25
		350	700

- Determine interactions between system water and glycol on phase behavior and activity coefficient.
- Evaluate the influence of potentially protective oil films
- Determine the influence of impurities such as chloride, oxygen, and elemental sulfur
- Assess the probability for localized or pitting corrosion (Ref 29, 30)

As mentioned previously, an important innovation in corrosion prediction is the use of flow modeling to assess and understand the influence of production parameters on determining the applicable flow regime and quantify the resultant mechanical forces in terms of wall shear stress and their influence on protective corrosion films and ultimately on corrosion rates. Table 2 shows a summary of typical parameters used in software tools for corrosion prediction and their various effects and interactions.

When both H_2S and CO_2 are present, heuristics indicate that iron sulfide may be the dominant corrosion product scale when the $\text{H}_2\text{S}/\text{CO}_2$ ratio exceeds about $1/200$ (Ref 29, 30); sour-system considerations would then be expected to apply. Even in a strictly CO_2 system, iron carbonate may not always be the corrosion product. Magnetite may form instead. Figure 4 shows the stability fields expected for siderite and magnetite as a function of the redox potential (expressed here in terms of hydrogen fugacity) of the system (Ref 25). In actual experience, corrosion product scales are often found to consist of mixtures or layers of siderite and magnetite when CO_2 is dominant, whereas many sulfide compounds may form once the level of H_2S exceeds a critical level to dominate the corrosion processes.

Iron carbonate lacks conductivity and therefore does not provide an efficient cathode surface. Thus, the types of pitting mechanisms found in oxygenated and in H_2S -containing systems do not occur in a CO_2 -only system unless contamination occurs. Rather, generalized corrosion occurs at any regions not covered by the protective scale. The result is that on any bare (unfilmed) metal, the anodic and cathodic regions are so microscopically dispersed that salt—to provide conductivity—is not needed to achieve the very high corrosion rates predicted by Eq 1. This often leads to a condition referred to as mesa corrosion in which local, unfilmed areas of steel corrode actively at a high rate, but adjacent filmed regions remain uncorroded. This results in a characteristic corrosion pattern reminiscent of the mesas produced in rock by wind and water erosion (see Fig. 5).

Strong Acids

Strong acids are often pumped into wells to stimulate production by increasing formation permeability. For limestone formations, 15 and

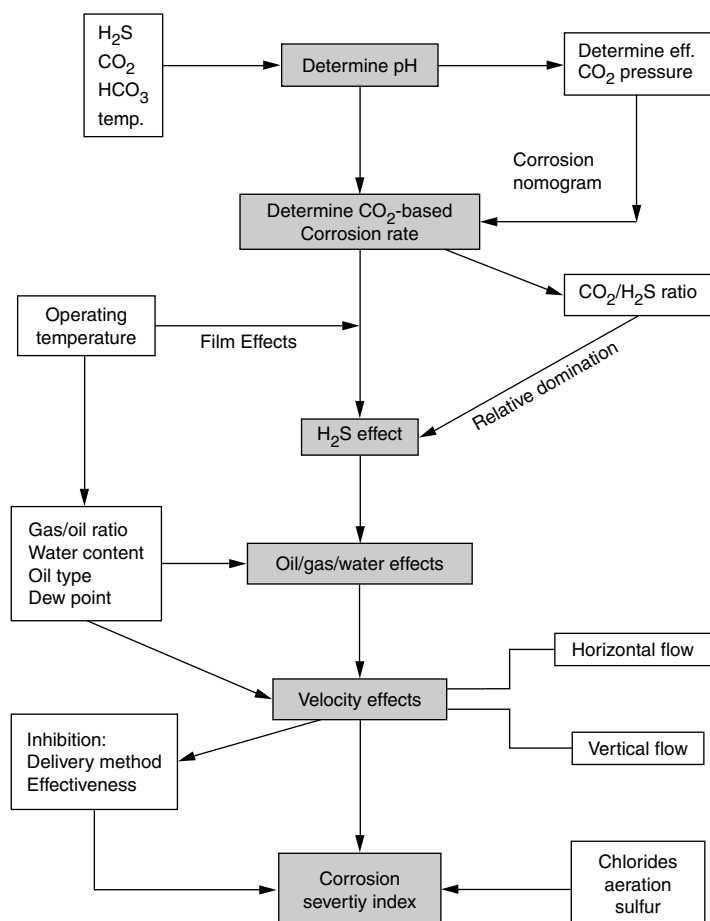

Fig. 3 Corrosion model software flowchart showing incorporation of multiple effects and variables. Source: Ref 29

28% HCl acids are commonly used. For sandstones, additions of 3% HF are necessary. In deep sour gas wells where HCl inhibitors lose effectiveness, 12% HCOOH has been used.

Corrosion control is normally achieved by a combination of proper inhibitor inhibition (different formulations for steels and corrosion-resistant alloys) and limiting exposure time to 2 to 12 h. If corrosion-resistant alloys are present (austenitic and duplex stainless steels, titanium alloys, and so on), concern for SCC and inhibitor ineffectiveness (respectively) may rule out the use of HCl, particularly at high reservoir tem-

peratures, unless advanced screening of inhibitor formulations is undertaken.

Concentrated Brines

Dense halide brines of the cations of calcium, zinc, and, more rarely, magnesium are sometimes used to balance formation pressures during various production operations. All can be corrosive because of dissolved oxygen or entrained air. In addition, such brines may be corrosive because of the acidity generated by the hydro-

lysis of the metallic ions, as illustrated in:

Corrosivity due to acidity is worst with dense zinc brines. More expensive CaBr_2 brines are now often used at densities above about 1.7 g/cm³ (14 lb/gal) (attainable with CaBr_2 brines) to avoid long-term exposure to ZnCl_2 brines.

Stray-Current Corrosion

If an extraneous direct current (dc) in the earth is traversed by a conductor, part of the current will transfer to the lower-resistance path thus provided. Direct currents are much more destructive than alternating currents (ac); an equivalent ac current causes only about 1% of the damage of a dc current (Ref 31). Regions of current arrival (where electrons depart) will become cathodic, and those regions where the current departs will become anodic. With corrosion-resistant metals such as carbon and low-alloy steels, corrosion in the anodic areas is the result. For example, 1 A·yr can corrode 9 kg (20 lb) of steel.

Cathodic protection systems are the most likely present-day sources of stray dc currents in production operations. More detailed discussions are available in Ref 12 and 32. The article "Stray-Current Corrosion" in Volume 13A of the *ASM Handbook* also contains information on the causes and mechanisms of stray-current corrosion.

Underdeposit (Crevice) Corrosion

This is a form of localized corrosion found almost exclusively (if not exclusively) in oxygen-containing systems. Such corrosion is usually most intense in chloride-containing systems, but can also be pronounced in aerated systems with active biological populations and biofilming to produce differential aeration cells. It is essential to have some form of shielding of an area on a metal such that it is wetted by an electrolyte solution but is not readily accessible to oxygen, the diffusing corrosive species.

This type of attack is usually associated with small volumes of stagnant solution caused by surface deposits (sand, sludge, corrosion products, bacterial growth), crevices in joints, and gasket surfaces. Crevice corrosion is discussed in Ref 33, and a quantitative treatment of crevice corrosion (particularly of stainless steels) is provided in Ref 34 to 36. See also the article "Crevice Corrosion" in Volume 13A of the *ASM Handbook* for information pertaining to the mechanisms of crevice corrosion.

The mechanism of crevice corrosion hinges upon the environmental conditions resulting from the loss of hydroxide production with cessation of the cathodic reaction when the initial oxygen in the shielded region is exhausted. Thus, in the shielded region, the anodic corrosion

Table 2 Flow-modeling parameters used to characterize flow-induced mechanical forces (wall shear stress)

Description	Relationship
1. Determine dimensionless parameters to describe fluid flow characteristics (e.g., Reynold's number, R_e) to account for mass transfer effects.	$R_e = \frac{\rho V D}{\mu}$
2. Determine friction factor, f , to account for pipe wall roughness (from Moody diagrams) in microturbulence on the surface of the pipe wall.	$f = f(R_e, e/D)$
3. Wall shear stress, τ , can be determined as a function of friction factor and other multiphase flow properties.	$\tau = \frac{f \rho V^2}{2}$
4. Determine flow regime (annular, stratified, bubble, slug, etc.) to estimate correction factors (e.g., for slug flow, Froude number, f_r , as a basis to estimate turbulent effects and intensity).	$f_r = \frac{V_t - V_s}{\sqrt{g h_{eff}}}$

Summary: Corrosion rate in fully developed turbulent pipe flows computed from field conditions of vertical or horizontal flow can be understood based on selected flow modeling parameters. Corrosion under field conditions can also be simulated in the laboratory. The results can be linked to field conditions using the parameter of wall shear stress where ρ is density, V is velocity, D is pipe internal diameter, and μ is viscosity. h_{eff} , effective height; g , acceleration of gravity; V_t , terminal velocity; V_s , superficial liquid velocity. reaction continues because the corrosion potential is maintained by the reduction of oxygen on the outside surface. However, chloride or other anions now migrate into the developing anodic region to maintain electroneutrality. Thus, a relatively concentrated, essentially ferrous chloride solution accumulates in the shielded region. As a result of the hydrolysis of the ferrous ions, the pH drops to a value of 2 or 3.

At this point, the crevice-corrosion type of localized attack is fully established. The anodic reaction continues in the shielded region because in the low-pH environment the ferrous ions go readily into solution and have little tendency to precipitate as an oxide or hydroxide on the surface and thus stifle the anodic reaction. Outside, the cathodic reaction continues unperturbed. Because of the large ratio of cathodic-to-anodic surface area, high rates of localized corrosion can be maintained with very modest cathodic current densities.

Galvanic Corrosion

When two dissimilar metals are electrically coupled—both electronically by a metal bond and ionically through an electrolyte—the more active (electronegative) metal tends to become a sacrificial anode and supply cathodic protection to the more noble metal. Such situations are often encountered in heat exchangers in which carbon steel tubesheets are used with copper alloy tubes and at junctions between piping, fasteners, or corrosion-resistant sheeting with containers of another material.

Problems with galvanic corrosion are the most acute when the cathode-to-anode area ratio is large. Such situations are often encountered inadvertently. This has happened when the normal electrochemical potential difference be-

tween zinc and steel in a galvanized pipe reversed in the presence of a bicarbonate/chloride brine so that the steel pipe walls perforated rapidly at pinholes in the galvanizing while trying to protect the extensive adjacent galvanized area. Similar situations can occur when using zinc to cathodically protect hot subsea pipelines where the polarity shift is a direct result of the increase in temperature. Another situation is when plastic-coated steel is coupled to a more noble metal. At any pinholes in the coating, a very adverse area ratio will exist, and rapid corrosion rates can result. Another common problem is when chromium or electroless nickel plated steels are used in corrosive seawater or oil-field production environments. Small cracks or crazes in the coatings allow communication of the corrosive fluids to reach the steel. In this case, the chromium or nickel coating covers a much larger area and has a higher electrochemical potential than the steel. This condition usually results in very rapid corrosion of the steel at local anodic sites that may, in some cases, actually consume the steel substrate. The article "Galvanic Corrosion" in Volume 13A of the *ASM Handbook* contains more information on this form of attack.

Biological Effects

The most important biological effect on corrosion in oil and gas production is the generation of H_2S by sulfate-reducing bacteria—SRB—(*Desulfovibrio Desulfuricans*). These are anaerobic bacteria that metabolize sulfate ions (using an organic carbon source) and produce hydrogen sulfide. They can thus introduce H_2S and all its corrosive ramifications into normally H_2S -free systems.

Colonies of SRB can also form deposits that are conducive to underdeposit corrosion. In

many cases, the resultant corrosion appears to be due to a mechanical shielding action (differential concentration or aeration), rather than any depolarizing action resulting from the metabolic processes of the SRB. However, this is not to deny that the introduction of H_2S (whatever the source) into a crevice region could have an accelerating effect on corrosion, because H_2S is known to be an acid gas and anodic stimulant leading to local increase in corrosivity. More information on biological corrosion is available in the article "Microbiologically Influenced Corrosion" in Volume 13A of the *ASM Handbook*.

Mechanical and Mechanical/Corrosive Effects

Cavitation. This metal removal—often grain by grain—is due to high-pressure shock-wave impingement resulting from the rapid collapse of minute bubbles created under certain conditions in high-velocity fluid-handling equipment. It is usually found on pump impellers operating with too low a suction pressure.

Erosion. Most commonly, this is direct metal removal by the cutting action of high-velocity abrasive particles. Erosion failures (washouts) are seen in drill pipe when leaks (loose connections or a corrosion fatigue crack) allow drilling mud with fine particulates to flow through the wall under a high-pressure gradient. Erosion of oil and gas gathering lines at bends and joints or in flow-control valves and wellhead equipment by produced sand is probably the other most common occurrence of erosion in oil and gas production.

Erosion-Corrosion. Strictly speaking, in erosion-corrosion, only the protective corrosion product film is removed by erosive forces; however, with the protective film absent, corrosion can occur at a greatly accelerated rate. Erosion-corrosion may play a role in CO_2 corrosion (Ref 37), and sand, under mild flow conditions, may also cause erosion-corrosion. Design problems resulting in rapid changes in flow direction, neck-down points, or local turbulence can also lead to erosion-corrosion problems in production systems. Production conditions involving multiphase (oil/gas/water) flow can also result in erosion-corrosion since conditions of liquid and gas flow resulting in slug flow or mist flow can produce quite severe levels of wall shear stress. Erosion-corrosion has also been noted in heavy anchor chains where their use in an abrasive bottom mud allowed corrosion at contact regions to proceed at a rate of many hundreds of mils per year.

Corrosion Fatigue. This results from subjecting a metal to alternating stresses in a corrosive environment. At points of greatest stress, the corrosion product film becomes damaged during cycling, thus allowing localized corrosion to take place. Eventually, this leads to crack initiation and crack growth by a combination of

mechanical and corrosive actions. Because of this combined action, damage per cycle is greater at low cycling rates (usually at less than 2 Hz with increasing effect with decreasing frequency), where corrosion can play a larger role. Also, in corrosion fatigue, counter to the usual case for steel in noncorrosive applications, a fatigue limit does not exist for corrosion fatigue, below which fatigue damage does not accumulate. Rather than leveling out as in simple (noncorrosive) fatigue, the usable stress level continues to decrease with increasing cycles even at very low levels of applied stress.

The greatest concern for corrosion fatigue arises in connection with highly stressed, submerged, offshore structures. Corrosion in seawater combined with cyclic loading can result in corrosion fatigue. In some conditions, corrosion fatigue can also occur under conditions of cathodic protection in seawater. In this case, the culprit is the hydrogen produced on the metal surface by the cathodic protection. Materials most susceptible to this phenomenon usually are those that have a particular sensitivity to hydrogen. These are commonly high-strength steels and weldments, martensitic and duplex stainless steels, and in some cases, highly alloyed materials such as nickel-base alloys (e.g., alloy 718 and titanium alloys). It has been recently observed that deep water conditions may be particularly of concern for hydrogen charging due to the lower temperatures and associated tendency to form calcareous deposits on materials being cathodically protected. In applications involving deep water drilling, increased stress levels, increased run time, use of high-strength/hardness materials, and higher cathodic protection currents can lead to conditions of hydrogen embrittlement and corrosion fatigue. Welded connections on drill ships and on drilling and production platforms are particularly susceptible to this form of structural impairment.

More information on attack resulting from combined corrosion and mechanical effects is available in the article "Forms of Mechanically Assisted Degradation" in Volume 13A of the *ASM Handbook*.

Additional information on these methods, as well as other corrosion protection techniques, can be found in Volume 13A of the *ASM Handbook*.

Materials Selection

Traditionally, carbon and low-alloy steels were virtually the only metals used in the production of oil and gas. This resulted from the fact that very large quantities of metal are required in petroleum production, and, until a few years ago, crude oil and gas were relatively low-value products. In addition, insurmountable corrosion problems were not encountered.

This situation changed when gas and oil prices increased dramatically and deeper wells were drilled that encountered corrosive environments of greatly increased severity. The final factor that made the current widespread use of corrosion-resistant alloys possible was the development of high-strength forms of these alloys. This allowed both thinner pipe and vessel walls and greatly reduced the amount of material required.

The result of this situation is that essentially all of the high-tonnage uses of corrosion-resistant alloys in oil and gas production involve alloys in a high-strength form. Yield strengths typically span the range of 550 to 1250 MPa (80 to 180 ksi), but can reach nearly 1750 MPa (250 ksi) in wire lines.

Metallurgical Considerations

The great majority of corrosion-resistant alloys used in oil and gas production were originally developed for other applications, such as chemical processing, that did not require high strength. Therefore, many of these alloys have an austenitic microstructure and can be strengthened only by some form of cold working. This presents no problem for the production of tubulars used underground in the well because they are joined by threaded connections. However, for other applications, such as welded flow lines and cast and forged valves, different techniques must be used to achieve high strength. Other higher-strength alloys initially used for downhole applications were developed for high-temperature aerospace applications and did not have substantial consideration for aqueous corrosion. However, since the first pioneering uses of these corrosion-resistant alloys in oil-field applications in the 1970s, further research and development has occurred, which has brought new alloys and processing methods that provide higher strength, resistance to H₂S and CO₂ corrosion, and resistance to various forms of EAC.

In addition to the problems of environmental compatibility, there are a number of difficulties of a metallurgical nature that are briefly mentioned. For high-strength materials, particularly at the upper end of the range, adequate ductility is often difficult to achieve. Also, heat treatments developed for other applications may not be

optimal for corrosion resistance in petroleum environments.

Environmental Considerations

There are several environmental factors that are more or less unique to oil and gas production. One factor is the general absence of oxygen in process fluids. The dominant naturally occurring corrosives are CO₂ and H₂S. However, in wells with high H₂S concentrations, elemental sulfur—a relatively strong oxidizing agent—can also be present.

Water, which must be present to make sulfur or the acid gases (CO₂ and H₂S) corrosive, can be assumed to be present in nearly all productive geologic formations to varying degrees. Therefore, liquid water can be present from the bottom of the well up to the point in the flow system at which it is removed. Corrosivity is aggravated by the presence of salt in formation waters. These brines can range from a few hundred parts per million chloride up to saturated solutions containing as much as 300,000 ppm of total dissolved salts.

However, a salient consideration often overlooked is that formation water while containing chlorides often contains other species such as bicarbonate that can buffer the influence of acid gases and thus produce less acidic conditions that can mitigate corrosion. This is often the case in oil wells that produce varying amounts of formation water. By comparison, gas wells often produce condensed water that precipitates from the vapor phase. This condensed water usually contains little in the way of chlorides and buffering salts and may produce a highly acidic condition when in contact with H₂S and/or CO₂. Furthermore, in gas wells, naturally occurring organic acids may also be present in the production environment that further increase acidic conditions to levels that are more corrosive than those resulting from merely the CO₂ and H₂S (Ref 38).

At the same time, the conditions in the downhole annulus between production tubing and casing may contain concentrated brines with chlorides and bromides of sodium, calcium, and zinc. Additionally, exposure to strong mineral or organic acids may be used to stimulate oil and gas production from subterranean reservoirs. It should be realized that the corrosivity of these "nonproduction" environments can, at times, be more a determining factor for alloy selection than the corrosivity of the oil and gas production environment.

Temperature also affects corrosivity. Deep well temperatures up to 205 °C (400 °F) are not uncommon. Therefore, temperatures from these levels down to ambient must be considered.

Corrosion Considerations

From other applications, enough is generally known to select alloys that are resistant to general corrosion. However, resistance to localized

Corrosion Control Methods

The methods of corrosion control commonly employed in petroleum production operations include:

- Proper selection of materials
- Protective coatings
- Cathodic protection systems
- Use of inhibitors
- Use of nonmetallic materials
- Control of the environment

corrosion (pitting and crevice corrosion) often requires some experimental study, field experience, and/or use of modern computer software that utilizes parametric modeling of environmental parameters, alloy composition, and strength factors.

Environmentally Assisted Cracking. In corrosion-resistant alloy selection, EAC normally requires the greatest portion of consideration through testing and/or modeling. This follows from the use of high-strength alloys in environments in which there has been an acknowledged short history of application, but growing experiences with these alloys.

The term environmentally assisted cracking was selected because it includes multiple corrosion mechanisms: cathodic and anodic. The cathodic mechanism is that of hydrogen embrittlement found in sulfide stress cracking of high-strength carbon and low-alloy steels in the presence of hydrogen sulfide. Here, H_2S promotes entry of cathodically evolved hydrogen atoms into the metal. Additionally, many of the higher-strength steels, stainless steels, and nickel- and titanium-base alloys can also show susceptibility to hydrogen embrittlement under influence of galvanic coupling with dissimilar alloys and during cathodic protection.

The anodic mechanism is that involved in the chloride SCC of nickel-containing martensitic and 300-series austenitic stainless steels at temperatures generally above about 65 °C (150 °F). However, this temperature limit is only a general guideline for SCC and typically only rigidly applies in aerated systems. Actual susceptibility to SCC in oil and gas production varies with many parameters including chloride concentration, partial pressure of acid gases, pH of the brine, and temperature as well as alloy composition, metallurgical condition, and strength level. Higher resistance to SCC in stainless alloys is usually associated with higher alloying contents of nickel, chromium, molybdenum, and tungsten. Nickel-base alloys are normally considered immune to this type of chloride cracking. However, the presence of H_2S can induce susceptibility in normally resistant alloys by acting to promote local anodic dissolution. In the most resistant alloys, such as alloy C-276 (Table 3), elemental sulfur and a temperature of about 205 °C (400 °F) must also be present to cause SCC. The presence of elemental sulfur can accelerate cracking in most corrosion-resistant alloys since it also promotes local anodic attack that results in stimulating both the initiation and propagation of SCC. However, this type of SCC is most commonly associated with high-strength and/or heavily cold-worked materials; however, in lower-alloy stainless steels, this mechanism can also cause cracking in low-strength, fully solution annealed alloys at lower temperatures.

Effects in the Cathodic Mechanism (Hydrogen-Assisted Cracking). In corrosion-resistant alloys, environmental effects on cathodic stress cracking are generally similar to those encountered in the sulfide stress cracking of carbon and low-alloy steels. However, in

extreme cases, the temperatures needed to avoid hydrogen-assisted cracking susceptibility in the highest-strength materials can be as high as 120 °C (250 °F) or more. An example is alloy C-276 cold worked to a hardness of 45 HRC. In contrast, the highest minimum use temperature given in NACE standard MR0175/ISO 15156 (Ref 14) for high-strength low-alloy tubulars is 80 °C (175 °F).

Also, on corrosion-resistant alloys, chloride ions can have a significant deleterious effect in hydrogen-assisted cracking as well. This results from deterioration of normal passivity of the alloy in the presence of chloride. The resulting higher local anodic corrosion rate can then support a higher rate of cathodic corrosion processes and thus give rise to enhanced cathodic charging of the corrosion-resistant alloy with atomic hydrogen.

The present philosophy used in handling resistance to sulfide stress cracking of steels and stainless alloys is to incorporate parameters such as H_2S concentration and pH for a given temperature. Sulfide stress cracking susceptibility is usually assumed to be greatest at or near 23 °C (75 °F). Figure 6 shows data for 13% Cr martensitic stainless steels plotted in this manner (Ref 39). It defines levels of cracking severity that generally increase with decreasing pH and increasing H_2S concentration. The actual susceptibility to hydrogen-assisted cracking at lower temperatures has not been fully examined, but limited data suggest that there is a temperature for maximum hydrogen cracking susceptibility that is somewhat below room temperature.

Effects in the Anodic Mechanism (Stress-Corrosion Cracking). Determining regions of susceptibility to anodic cracking is generally

more complicated than defining regions of susceptibility to cathodic (hydrogen) cracking. This is due to the multiparametric nature of the problem (Ref 40). Therefore, in anodic SCC, susceptibility is a strong function of such environmental factors as temperature, chloride concentration, and H_2S partial pressure; in addition, pH, oxidants (elemental sulfur or polysulfide), oxygen, and galvanic coupling can be involved. Further, alloy composition (corrosion resistance), strength level, and stress level all influence cracking susceptibility.

The effect of H_2S requires some elaboration. In cathodic cracking, there is a well-established threshold for the initiation of the sulfide stress cracking phenomenon; this lends itself to be examined in a relatively short test under static load. This is not always the case in anodic cracking. Susceptibility to SCC has a stronger chemical component and often requires a very long time for cracking initiation under static loading conditions. In order to properly evaluate for SCC susceptibility, local anodic processes must be accelerated either by chemical or mechanical procedures. Since this form of cracking requires assessment of the overall severity of the environment, it is more common to try to correctly simulate the severity of the actual corrosive environment in service, while accelerating cracking through application of mechanical loading (e.g., slow strain rate tests, cyclic slow strain rate tests, and sharp crack fracture mechanics tests).

Selection of Corrosion-Resistant Alloys

The problem of alloy selection to prevent EAC cracking is complicated by the fact that the

Table 3 Compositions of commonly used oil field corrosion-resistant alloys

(a) Maximum unless range is given or otherwise indicated

lowest alloy content and the maximum reliable strength level are usually needed to achieve an economically viable engineering system. Because this involves design close to the limits of the material, it is necessary to define these limits as accurately as possible. The currently available service environment limits for corrosion-resistant alloys (Table 3) are given in NACE MR0175/ISO 15156 (Ref 14). However, such limits are not readily available for all alloys. As more experience and test data have become available, it has been possible to construct computer software models that can assist engineers in the materials selection process by application of data, rules, and algorithms in a systematic manner (Ref 41). Such software tools have also incorporated references to standard American Petroleum Institute (API) equipment configurations for wellhead and subsurface safety equipment, thus facilitating material selection, specification, and eventual purchasing by nonmaterials specialists. This allows the materials specialists to focus attention and valuable staff time on the most serious problems that may arise either before or after procurement.

Alloy selection from a corrosion standpoint can be considered to be generally a three-step process. First, resistance to general corrosion must be ensured. This is primarily a function of the chromium and nickel content of the alloy and under a first consideration may be associated by alloy classification: martensitic, austenitic, and duplex stainless steels, nickel-base alloys, and titanium alloys. Secondly, resistance to localized attack also must be ensured. This is primarily a function of chromium and molybdenum content, but recent alloy developments have also shown an influence of other alloy elements that help maintain passivity. These alloying elements include tungsten and nitrogen. Finally, resistance to environmental stress cracking is sought at the highest feasible strength level. Nickel content plays an important role in providing resistance to anodic cracking. However, it is realized that under conditions of anodic SCC in environments with chlorides and H_2S , the initiation of cracking is usually more closely associated with pitting corrosion. Therefore, alloying effects for cracking in most materials actually follow similar trends to those mentioned for localized corrosion but with additional guidelines for strength and metallurgical condition.

The close correlation between pitting resistance and resistance to anodic cracking is an important aspect with considerable importance in alloy selection. This apparently results from the ease of crack initiation under the low-pH high-chloride conditions found in pits. Therefore, higher molybdenum, tungsten, and nitrogen in combination with chromium can also increase resistance to anodic cracking.

With the procedures given below, regions for alloy applicability can be shown schematically as a qualitative function of environmental severity. Figure 7 is a simple example that applies to aqueous, CO_2 -containing environment

(hence low pH) and in which the effects of temperature, chloride, and H_2S concentration are illustrated. The effect of yield strength is not shown, but if environmental cracking is the limiting factor, reducing the yield strength should extend applicability to more severe environments.

The reader should be cautioned that a diagram such as Fig. 7 is really more of a guide to alloy qualification than to direct selection for a parti-

cular application. More complex analyses that can apply a more complete parametric approach are required to give specific recommendations for field situations.

More recently, this approach has been broadened to include the full range of conditions in H_2S and CO_2 production environments through materials selection software. Figure 8 shows a schematic of the hierarchical approach. This approach is called selection

Fig. 6 Effect of H_2S partial pressure and pH and susceptibility to SSC for 13% Cr martensitic stainless steel tubular grades. Source: Ref 39

Fig. 7 Corrosion-resistant alloy selection for production environments containing aqueous CO_2 and H_2S

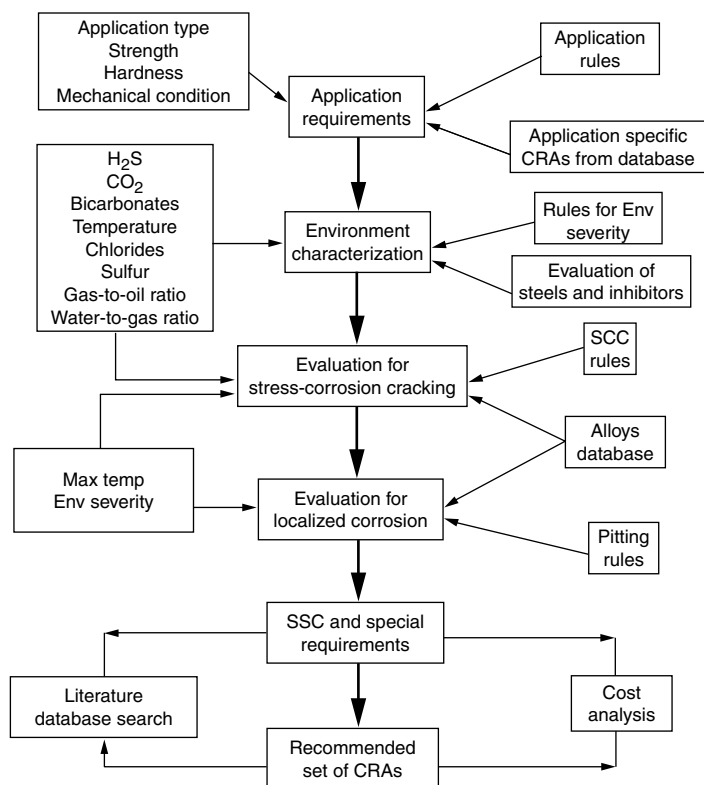

Fig. 8 Hierarchical decision tree for use in developing software tool for materials selection of oil and gas service applications. CRA, corrosion-resistant alloy; Env, environment; SCC, stress-corrosion cracking; SSC, sulfide stress cracking. Source: Ref 41

of corrosion-resistant alloys through environmental specification, and it involves:

1. Application requirements—strength, hardness, and mechanical attributes
2. Characterization of environment— H_2S and CO_2 partial pressures, chlorides, bicarbonates, sulfur, oil properties, and water availability
3. Evaluation for SCC—mostly by alloy class and composition
4. Evaluation for pitting—use of rules based on required minimum pitting resistance indices incorporating factors for chromium, molybdenum, tungsten, and nitrogen
5. Evaluation of sulfide stress cracking and hydrogen-assisted cracking
6. Cost analysis
7. Final selection of material

This procedure is widely utilized by end users to select materials and by materials suppliers and equipment manufacturers to handle inquiries. More recently, a similar approach has been utilized by industry standards such as NACE MR0175/ISO 15156 (Ref 14).

Testing for Resistance to Environmental Stress Cracking

If through the use of computer models for materials selection, it is ascertained that the conditions of use may be marginal for certain

materials, or if special metallurgical considerations must be evaluated, the most directly applicable results are obtained by exposing samples of commercially produced alloys to an environment simulating as closely as possible that expected in actual production operations. Fortunately, an understanding of the principles involved allows considerable simplification to be made without significantly altering the value of the results.

Two simplifications can usually be made in the environmental parameters, as follows. First, only the CO_2 and H_2S partial pressures (mole fraction \times total system pressure) are usually involved. The overburden of methane pressure to create the actual total pressure of the environment is dispensed with since they commonly have only very limited impact on the corrosive severity of the environment. However, at very high pressures, the nonideality of the gases can influence and limit the actual amount of acid gases that dissolve in the aqueous media and lead to overly conservative evaluations. The omission of the methane from the system can substantially lower the pressure ratings of test vessels required for this evaluation. The cases where the total pressure needs to be simulated are where polymeric materials such as elastomers and plastics are being evaluated or where the specific phase behavior of the system plays a major impact in the solubility of the dissolved gases. Modeling software is available to evaluate the latter effect

to determine the appropriate partial pressure to use in laboratory autoclave tests. Second, only the chloride content of the brine is typically reproduced, rather than trying to simulate the total ionic spectrum of the produced fluids. Often, no reliable analysis is available. Assumption of a near-saturated sodium chloride solution (25 wt%) is then a relatively conservative approach, but where chloride levels in the produced water have been verified, these values will provide the most accurate indication of corrosive tendencies.

More recently, emphasis has been to also reproduce the bicarbonate levels so that a more appropriate pH level will be obtained in the aqueous phase when it is combined with the partial pressures of H_2S and CO_2 , which reduces the level of conservatism. In some cases, the presence of a liquid hydrocarbon phase is also included, which often reduces the conservatism still further if persistent oil films are formed on metal surfaces. However, in this case, the phase behavior and flow conditions of the actual production environment need to be considered so that it is known if the water/oil mixture will remain emulsified or if it will disassociate, leaving a separate water phase. Additionally, specific liquid hydrocarbons can contain inhibitive compounds that will dissolve into the aqueous phase and, in some cases, substantially reduce the severity of corrosion, SCC, and SSC.

A wide variety of test specimens used for SSC and SCC testing and can be found in NACE TM0177 (Ref 42). For high-strength corrosion-resistant alloy tubulars, C-rings (NACE TM0177-Method C) are particularly convenient because they provide an easy way to obtain specimens that are stressed in the transverse (hoop) direction, that often shows higher susceptibility to cracking in many cold-worked alloys. They also have the advantage of providing as-produced tube inner diameter (ID) or outer diameter (OD) surfaces, if needed. Some investigators, however, prefer tensile specimens (NACE TM0177-Method A) since they provide a simple test approach and a uniform stress across the gage section. Double cantilever beam specimens (NACE TM0177-Method D) are very attractive in that they can provide a quantitative measure of fracture toughness, which can then be used in mechanical design. They also provide an extremely high value of initial stress intensity that can act to initiate cracking in a relatively short period of time.

Slow strain rate testing (NACE TM0198) can also be very useful in assessing alloy limits (Ref 43). The application of a dynamic load and high plasticity acts to accelerate crack initiation particularly when anodic SCC processes are involved. However, this test method needs careful evaluation since it can produce exceedingly high susceptibility in some materials, particularly those with martensitic or duplex microstructures. In some of these cases, the slow strain rate test can be modified (per ASTM G 129) to include application of slow cyclic loading ($\pm 10\%$ around a mean stress) (Ref 44). In this case, the

cracking is accelerated by the dynamic loading, but does not respond to the negative influences of the high plasticity in the conventional slow strain rate test. This test can also be used to produce a "threshold" similar to that of the statically stressed specimens such as tensile, C-rings, and bent beams (Ref 45).

Another aspect of testing is the imposed stress level. Exposure at 100% of yield strength is the conservative approach. However, some investigators and industry standards place reliance on design values and test at some lesser fraction of the yield strength (80 to 95%) or of the specified minimum yield strength for the alloy grade. Detailed information on testing for resistance to environmental cracking is available in the articles "Evaluating Hydrogen Embrittlement" and "Evaluating Stress-Corrosion Cracking" in Volume 13A of the *ASM Handbook*.

Coatings

Internal protective coatings have been used to protect tubing, downhole equipment, and well-head components. Christmas trees (manifolds used to control the rate of production, receive the produced fluids under pressure, and direct the produced fluids to the gathering point) and various downstream flow lines and pressure vessels for more than 50 years. Because internal coatings are not commonly considered "perfect" barriers to corrosion and are often subject to damage or deterioration over time, successful use is usually accompanied by chemical inhibition or cathodic protection as part of the entire protective program. Most of the coatings have been used below 175 °C (345 °F).

Tubing. The benefits derived from coating tubing depend on the coating remaining intact. Because no coating can be applied and installed 100% holiday-free, inhibition programs are commonly employed to accommodate holidays and minor damage. The suitability of the service is dependent on specific testing and an effective quality-control program. Guidelines for these procedures and methods are given in various NACE specifications:

- NACE TM0185-2000, "Evaluation of Internal Plastic Coatings for Corrosion Control of Tubular Goods by Autoclave Testing"
- NACE RP0181, "Liquid-Applied Internal Protective Coatings for Oilfield Production Equipment"
- NACE RP0188, "Discontinuity (Holiday) Testing of Protective Coatings"
- NACE RP0490, "Holiday Detection of Fusion-Bonded Epoxy External Pipeline Coatings of 250 to 760 mm (10 to 30 mils)"
- NACE RP0191, "The Application of Internal Plastic Coatings for Oilfield Tubular Goods and Accessories"
- NACE RP0394, "Application, Performance, and Quality Control of Plant-Applied, Fusion-Bonded Epoxy External Pipe Coating"
- NACE TM0183, "Evaluation of Internal Plastic Coatings for Corrosion Control of Tubular Goods in an Aqueous Flowing Environment"

On a practical basis, one of the most misunderstood aspects of using coatings is that the inhibitor dosage will not usually change even though an operator decides to use coated tubing versus that used for bare tubing. However, the use of coated tubing does improve the protection in shielded areas that are inaccessible to inhibitors. It also reduces the exposed area of corroding steel and therefore also reduces the amount of corrosion products in the system.

The two greatest dangers to coated tubing are wireline damage and improper joint selection. Wireline damage can be minimized by adjusting running procedures to include wireline guides and to slow wireline speed (<0.5 m/s, or <100 ft/min). Inhibiting immediately after wireline work is also good practice in an attempt to establish protection of any fresh, exposed metal. Proper joint selection involves choosing a joint that allows the coating to be applied around the pin-end nose into the first few pin threads and from the first few coupling threads into the coupling body. The proper joint allows the coating to remain undamaged. Often, a corrosion barrier compression ring is used to accomplish this end. Joint designs that involve metal-to-metal sealing are not joints that can be coated.

The coatings used for tubing protection are polyurethane, phenolformaldehyde, epoxized cresol novolac, and epoxy resins. Suitability for service is and should be based on laboratory testing or substantial service experience in the specific environment and at the temperature proposed for the service.

The quality-control parameters of concern are tubing surface finish/preparation, application techniques, coating thickness, holiday detection, joint condition, and inspection. By far, most coating failures are related to application procedures and not from incompatibility with well fluids or thermal degradation. Inspection is required to ensure the suitability of the surface preparation and coating process. Quality control and surveillance are as much a part of a successful protective coating program as choosing the appropriate coating. The production coating must be applied in the same way the coating was applied to the test specimens, and a good coating specification and third-party inspection are important. Coated pipe and couplings must be carefully handled after coating, during shipping, in storage, and at the well site. The threads must be protected from impact with other pipe and objects.

Wireline work is necessary. These operations can be accomplished with a minimal amount of damage to the tubing if certain details are attended to:

- Wireline speeds are kept to 0.5 m/s (100 ft/min) or less.
- All sharp edges are removed from the tools.

- All tools are plastic coated or covered with a plastic sleeve.
- Wheeled centralizers are used on all center hole jobs.

Using the above precautions, many wireline trips can be made with little or no damage. The fact that coating should not be used because the wireline will cut the coating and cause accelerated corrosion in the wireline track is not true. When the wireline cuts uncoated tubing, it exposes the underlying steel. In properly coated tubing, the coating electrically insulates the cathodic areas so that the corrosion rate in the track is essentially the same as that for uncoated steel without wireline damage.

Wellheads, Christmas Trees, and Downhole Equipment. The exposed surfaces of well-head equipment, Christmas trees, and downhole equipment must be treated with inhibitor, but are often coated or manufactured of corrosion-resistant materials. The tubing hanger is threaded onto the production tubing and continues through the tubing bonnet (tubing adapter), the master valve(s), the tee or cross, and the wing and crown valve(s) and into the choke. Ring gasket grooves, valve seat pockets, and other compression fitted parts must not be coated. These areas can be overlaid with corrosion-resistant alloys, and the coating can be applied over a transition area up to the corrosion-resistant alloy overlay. Valve internal cavities need not be coated if corrosion is otherwise under control.

Generally, tubing hangers are difficult to coat and are therefore made of corrosion-resistant alloys for corrosive service. Hangers without back-pressure valve threads can be coated, but the cost of coating the carbon steel hanger may be equivalent to the cost of a corrosion-resistant alloy hanger.

Downhole equipment (nipples, polished bore receptacles, seal subs, tie backs, millout subs, packers, and so on) use the same standards as tubing. Most downhole equipment is considered uncoatable because it was not designed for coating, and corrosion-resistant alloys are often used. Such equipment can be coated as an assembled unit, rather than as individual pieces. If installation is below the packers, both internal and external surfaces should be coated or corrosion-resistant alloys should be used.

Coated surface flow lines usually employ flanges or threads and couplings to join them. Joining by welding damages the coating, and field-applied repair coating is not recommended, as it is often an area for future coating deterioration and corrosion damage.

Vessels must be designed as a coated vessel or employ corrosion-resistant alloys. Coating a vessel that was not designed for coating is rarely successful. Vessel design for coating involves welded hangers for anodes in the fluid zone, flanged access, removable internals, smooth internal surfaces, and good access to all internal surfaces to be coated. As a general rule, coating over bolted assemblies is not successful.

Cathodic Protection

Corrosion occurs when an anode and a cathode are electrically connected in the presence of an electrolyte, and electrical currents leave a corroding metal and go into an electrolyte. A dc power source (or a metal that has a greater affinity toward corrosion) can be connected to the corroding metal and used to oppose these corrosion currents. If either of these produce currents sufficient to fully oppose the anodic corrosion current, the metal will be protected from corrosion. This technique is known as cathodic protection. The entire metal surface is converted into a cathode, while the corrosion currents are transferred to an auxiliary anode or sacrificial anode in which corrosion can proceed. Cathodic protection has been used in the oil field to protect pipelines, well casings, tanks and production vessels, and offshore platforms. More information on principles and applications of cathodic protection is available in the article "Cathodic Protection" in Volume 13A of the *ASM Handbook*.

Types of Cathodic Protection Systems

The two methods of applying cathodic protection discussed previously are: the sacrificial anode method and the impressed-current method. Because some metals are less noble (more electronegative) than the most common oil-field material—steel—in the galvanic series, they will become the anode (site of corrosion attack) when coupled to steel in the presence of an electrolyte. The most common of these materials are magnesium, zinc, aluminum, and similar alloys; these are called sacrificial anodes. These types of anodes are used when:

- Current requirements are relatively low.
- Electric power is not readily available.
- Short system life dictates a low capital investment.

The anode is usually electrically connected by a wire or steel strap to the structure to be protected. Magnesium and zinc are usually used in soils, while zinc and aluminum alloys can also be used in brine environments.

In the impressed-current method, an external energy source produces an electric current that is sent to the impressed-current anodes. The most common types of these materials include graphite, high-silicon cast iron, lead-silver alloy, platinum, and even scrap steel rails. These types of anodes are used when:

- Current requirements are high.
- Electrolyte resistivity is high.
- Fluctuation in current requirements will occur. These types of systems can be adjusted to compensate for varying current requirements.
- Electrical power is readily available, although this is not now as severe a limitation as it was in past years.

In a typical impressed-current system, ac from a power line flows into a rectifier where it is converted into dc. The dc then flows to the anode groundbed. Other means of supplying this electrical current include solar energy and thermoelectric generators. These methods are applicable at locations where conventional electric power is not economically available.

Solar energy has powered cathodic protection for well casings in Kansas (Ref 46) and Saudi Arabia (Ref 47); segments of a 480 km (300 mile) long, 0.8 m (32 in.) pipeline in Libya (Ref 48); and segments of a natural gas distribution system in Washington (Ref 49). In these systems, silicon semiconductor devices convert sunlight directly into dc electricity, which is then used for the anode groundbed and to charge batteries. These batteries provide current to the anode groundbeds during periods of little or no sunlight. The batteries must be checked periodically for proper electrolyte levels. Solar panels can be easily replaced or increased to attain a higher current output because they are fabricated in modules.

One oil company has used solar energy to protect about 800 well casings in western Kansas. The solar panels consist of individual silicon solar cells connected in series to form modules. These modules are then connected in parallel to form a panel that is rated at about 12 A and 4 V. Because the well casing in this field requires 1 to 2 A for cathodic protection, 2 V, 500 A·h lead-acid batteries are used. A rheostat controls the rate of current flow from the batteries, and the voltage regulator controls the battery charge rate. The batteries can provide electrical current to the anodes for 10 days even if the sun is completely blocked.

Another electrical current source is the thermoelectric generator. One type of thermoelectric generator is a system that uses a burner to heat an organic liquid in a vapor generator. This vapor then expands through a turbine wheel, thus producing power to a shaft to drive an alternator, where ac power is produced. The vapor then passes through a condenser where it is cooled and condensed back into a liquid to start the cycle again. The ac power is sent to the rectifier to be converted to dc. Figure 9 shows an illustration of this type of thermoelectric generator. These systems can produce a maximum of 80 A at 21 V (Ref 50).

Application of Cathodic Protection to Oil-Field Equipment

Pipelines. Cathodic protection of pipelines is very common in oil-field operations. As discussed previously in this section, sacrificial anodes or impressed current can be used for cathodic protection (Fig. 10). If the pipeline is well coated and not very long, the current requirements will probably be achieved with sacrificial anodes. If bare, a steel pipeline could require 1.1 mA/m² (0.1 mA/ft²) in soil, while a very well coated pipeline could require only

0.003 mA/m² (0.0003 mA/ft²) or less for cathodic protection (Ref 51).

The resistivity of soils (and therefore their corrosivity) will also vary with location. Differences in aeration, soil composition (sand or clay), and the presence of chemical spills are just a few of the factors that will affect the corrosivity of the soil. Sometimes, the resistivity of the surface soils is so high that conventional groundbeds (1.8 m, or 6 ft, deep) cannot be used. Conventional groundbeds are normally used when the soil resistivities near the surface of the ground are less than 5000 $\Omega \cdot \text{cm}$ (Ref 52–54).

In high-resistivity soils, deep groundbeds can be used where the anodes are installed vertically in holes at depths of 15 m (50 ft) or more. Deep groundbeds (Fig. 11) are normally used to provide a better distribution of current than conventional groundbeds. These types of groundbeds also minimize right-of-way problems and are essentially unaffected by seasonal moisture variations. They are more expensive to install than conventional groundbeds, and it is usually impossible to repair any damage to the cable insulation. These systems use the same type of anodes as the conventional groundbeds. The major difference is that a perforated vent pipe can be installed to prevent chlorine gas from accumulating around the anodes. If these gases collect around the anodes, they form an insulating barrier that increases the resistance of the groundbed and eventually causes the groundbed to become ineffective.

Well Casings. The first step in externally protecting a well casing is to cement through any corrosive zones. Cement acts as a coating and will significantly reduce, but not completely stop, corrosion of the casing. Therefore, cathodic protection is needed to supplement the cement coating (Fig. 12). The experience of one company with the cathodic protection of well casings showed an 88% success rate in preventing predicted casing failures (Ref 55). Although a single anode bed for a buried pipeline may protect as much as 80 km (50 miles), the maximum amount of casing that needs to be protected usually does not exceed 2.4 to 3.2 km (1.5 to 2 miles). One company coated nine casing strings in 3500 m (11,500 ft) wells with fusion-bonded epoxy in Florida (Ref 56). The coating was used to reduce current requirements and to improve current distribution. Uncoated casing strings were protected with 22 to 25 A, and even then there was incomplete corrosion control. Only 10 A were needed to protect the coated casing. Some of these casing strings were pulled because of other operational problems, and the coating was found to be in excellent condition.

Another method of reducing the current requirement is to place an insulating joint in the flow line at the wellhead. This joint prevents current from the flow line from flowing into the wellhead and down the casing. This current would leave the casing at low-resistivity zones (Ref 54–56).

Two methods are generally used to determine current requirements for well casing: casing

Fig. 9 Thermoelectric generator used to power cathodic protection systems in remote locations. Source: Ref 50

potential profile and E -log I . The casing potential profile is measured by using a tool that consists of two spring-loaded probes approximately 7.6 m (25 ft) apart. This tool is pulled through the casing, and voltage readings are taken between the probes as they contact the casing every 15 or 30 m (50 or 100 ft). A plot of potential versus depth is made (Fig. 13). A slope upward and to the left indicates an anodic area, while a slope upward and to the right indicates a cathodic area. Current from a temporary groundbed is then applied to the casing for protection, and another potential profile is taken. Current is increased until the profile slopes are upward and to the right. Providing a profile slope to the right does not necessarily mean that

all of the casing is protected, but it does mean that all gross corrosion areas have been eliminated.

Another technique for determining the required current is the E -log I curve. It is less expensive and does not require the disturbance of subsurface equipment. The flow line to the well, however, must be isolated from the well casing. The pipe-to-soil potential relative to the Cu-CuSO_4 reference electrode is measured, and a small amount of current from a temporary groundbed is applied. The current is then interrupted, and the pipe-to-soil potential is measured as quickly as possible. The current is then increased a small amount, and the process is repeated to obtain a curve similar to that shown

in Fig. 14. Generally, the current required corresponds to the break in the curve.

Tanks and Production Vessels. Internal corrosion of water-handling tanks and vessels can be controlled by the use of cathodic protection. Even if a coating has been applied to the interior of a water storage tank, there will always be imperfections where corrosion can occur; therefore, cathodic protection is needed. Sacrificial anodes can be suspended from the top of the tank as shown in Fig. 15 to offer protection to the portion of the tank that is covered with water. Cathodic protection will not help in the vapor area of the tank. Coatings must be used to protect this area. Sacrificial anodes have also been placed on concrete blocks in tanks. These blocks insulate the anode from the tank and allow decomposition products to fall away from the anode. In most cases, a lead wire is brought outside of the tank and welded to the tank. These anodes should also not be allowed to touch the sides of the tank and should be uniformly distributed within the tank to give uniform current distribution.

In vessels that have several sections separated by steel plates, the anodes might be shielded from protecting the entire vessel. In these cases, the only safe procedure is to install an anode in each compartment. Similar tanks without cathodic protection in one southern Texas field failed from corrosion in 3 months (Ref 57, 58). When ac power is available, impressed-current systems using high-silicon cast iron, graphite, or platinized titanium anodes in through-the-wall mounts have also been used. Crude oil and some oil-field chemicals have tended to stifle the flow of current from these anodes.

Offshore Platforms. The subsea zone of an offshore platform includes the area from the splash zone down to and including the pilings below the mudline. Cathodic protection is the principal means of preventing corrosion in this zone, but some companies also use coatings in conjunction with cathodic protection (Ref 59). The amount of electric current required to protect the bare steel varies with location. Typical current density values range from 54 to 65 mA/m^2 (5 to 6 mA/ft^2) in the Gulf of Mexico, 86 to 160 mA/m^2 (8 to 15 mA/ft^2) in the North Sea, and as high as 375 to 430 mA/m^2 (35 to 40 mA/ft^2) in the Cook Inlet (Ref 51). Current densities in the Cook Inlet are high because of the 8 knot tidal currents and entrained particulate matter experienced at this location. In the mud zone, current densities of 10.8 to 32 mA/m^2 (1 to 3 mA/ft^2) are needed for protection, and an allowance of 3 A per well is customary for well casings (Ref 60).

Additionally, there are also concerns for cathodic protection requirements for drilling and production applications in deep sea applications. Under these conditions, the seawater is at low temperatures, around 4 to 8 °C (40 to 50 °F), and the formation of calcareous deposits is retarded due to the increase in solubility of calcium carbonate in the colder seawater (Fig. 16) (Ref 61). This has the effect of increasing cathodic

protection current requirements. In some cases, conventional sacrificial anode cathodic protection is supplemented by the application of thermal sprayed aluminum coatings on the surface of steel members and equipment. Under such conditions, environmental factors, such as oxygen

content, water salinity, temperature, velocity, erosive effects, marine growth, and calcareous deposits, are largely responsible for the differences in current densities. It is very important that the current demand be conservatively estimated as retrofitting of cathodic protection sys-

tems in deep water applications can be prohibitively expensive.

Partial protection of the steel in seawater usually means that the area of corrosion is reduced, while the unprotected areas continue to corrode at a high rate. Some companies report

Fig. 10 Typical cathodic protection installations. (a) Impressed current. (b) Sacrificial anode

Fig. 11 Typical deep groundbed cathodic protection installation. Source: Ref 53

Fig. 12 Cathodic protection installation for a well casing. Source: Ref 54

pits as deep as 13 to 16 mm (0.5 to 0.625 in.) and, in many cases, holes in platform members after less than 5 years on location without adequate cathodic protection. This result corresponds to a corrosion rate of 2.5 to 3.2 mm/yr (100 to 125 mils/yr) (Ref 62).

As in all applications of corrosion control on offshore platforms, the first step for cathodic protection in the subsea zone is design. Tubular members should be used whenever possible. Recessed corners in channels and I-beams are difficult to protect. Even crevices formed by placing channels back-to-back and noncontinuous welded joints cannot be protected. Bolted and riveted fittings should be avoided. Piping such as grout lines, discharge lines, water supply casings, and pipeline risers, if clustered around a platform leg, can cause shielding and interfere with the flow of cathodic protection current. If economically feasible, piping that is not necessary for platform operations should be removed. A minimum clear spacing of 1½ diameters of the smaller pipe should be provided, and coatings on the pipe can also be used to minimize shielding. Corrosion will be negligible on the internal surfaces of structural members that are sealed and have no contact with either the atmosphere or the seawater. During launch, some structural members are flooded for the life of the platform. To prevent any internal corrosion, the flooding valves should be closed

Fig. 15 Cathodic protection system for a water storage tank. Source: Ref 57

Fig. 16 Influence of temperature on solubility of calcium carbonate and magnesium oxide. Source: Ref 61

to isolate the flooded chambers from contact with fresh seawater or oxygen in the atmosphere.

Sacrificial Anode Systems. The early offshore platforms installed in the late 1940s and early 1950s used 45 and 68 kg (100 and 150 lb) magnesium anodes supported from horizontal braces. A low-carbon steel wire rope connected the anode to the brace. These anodes had a 2 year design life, which was normally shortened to 1 year or less because of hurricane or rough weather losses. These swinging anodes tangled with subsea braces, shorted, and rubbed the conductor wires to failure. A variable resistor was also connected in series with the anode and the connection at the brace. This resistor was used to regulate the current output of the anode to achieve maximum efficiency. Unfortunately, this system could never be maintained. Magnesium anodes in seawater have a high current output and corrode rapidly; therefore, they must be replaced frequently. This type of system has been discontinued for offshore use.

Zinc anodes have been used for more than 200 years. However, impurities, such as iron, were responsible for erratic performance. Virtually all zinc anodes are now fabricated from high-purity zinc meeting the military specification MIL-A-18001-H. More efficient aluminum anodes have also been developed. A Hg-Zn-Al alloy anode provides 2½ times more current output than a zinc anode on a pound-for-pound basis. However, concerns for mercury on sea life has led to the use of other compositions for high-efficiency aluminum (including aluminum with variable zinc content, and aluminum-indium anodes). These compositions are shown in Table 4 (Ref 63). An anode weight of 330 kg (725 lb) is common for the initial system, while 150 kg (325 lb) is common for the replacement system. Proper specification of alloy composition and control of alloying and impurities in the anode are essential for best performance.

The number of anodes needed depends on the size of the anode and its useful life. A design life of 20 years is common. The distribution of anodes is also important, because poor distribution and the use of too few anodes will result in underprotection, particularly at welded joints. Individual anodes should be mounted at least 0.3 m (12 in.) from the structure, or a dielectric shield should be used beneath them to improve the current distribution. Anodes should not be located in either the splash zone or on bottom bracings. The anode will not function properly if it is intermittently in and out of the seawater,

and mercury-containing aluminum anodes will passivate and not function if covered by mud. Some of the earliest anodes used were prone to being knocked off of the platform during installation because the standoff posts were either too small or did not provide adequate area for contact welding of the anode to the member. Gussets and doubler plates can help obtain better anode attachment. A large fraction of premature cathodic protection failures have been traced to an inadequate number of anodes installed or excessive losses during pile driving. Some of these losses during pile driving are due to poor weld quality in attaching the anodes to the members.

Impressed-Current Systems. In an impressed-current system, the three essential components are the rectifier, the anodes, and the cable joining them together. The anode materials include graphite, high-silicon cast iron, lead-silver, and platinum wound on a niobium rod. Permanently mounted anodes, retrievable anodes, and remote anode sleds have all been successfully used. Because anodes in impressed-current systems generally produce considerably more current than sacrificial anodes, there may be only 6 or 8 impressed anodes on a structure that might do the same job as 50 to 70 sacrificial anodes. The location of these impressed-current anodes is very important in order to ensure that adequate current distribution is obtained to cover the entire surface. The connecting wiring is the critical part of an impressed-current system, especially in the splash zone, where the cable can be subjected to severe wave pounding if it is not housed in a protective conduit. Even these conduits can be torn away from the platform during a hurricane if they have been underdesigned. It is often necessary to protect the structural member near the anode with fiberglass coating or a wrap called a dielectric shield. This shield prevents excessive current consumption at this area.

Whether sacrificial or impressed anodes are used, cathodic protection currents will promote the formation of hydroxyl (OH^-) ions at cathodic areas (the entire platform, it is hoped) and cause a pH shift in the seawater near the platform. Also, the concentration of calcium and magnesium ions tends to increase in the film of seawater over the cathode. As a result of these changes, the solubility of calcium carbonate and magnesium hydroxide is exceeded, and a calcareous coating is deposited. These mineral deposits provide the primary corrosion control, and the cathodic protection current demand

drops to a level sufficient to repair this coating when it is damaged. For example, if a current density of 540 mA/m² (50 mA/ft²) is applied to a platform for the first 5 days on location, protection can be maintained with a current density of 32 mA/m² (3 mA/ft²).

There appears to be less tendency for these mineral deposits to form in the deep ocean. In an experiment conducted by the U.S. Navy, sacrificial anodes were effective at providing cathodic protection to bare steel in seawater at depths of 1700 m (5600 ft) (Ref 64). However, the anodes were consumed more rapidly than if they were located near the surface. Because the pH is lower at great depths and the calcium carbonate concentration is below saturation, higher currents are required to achieve protection.

Inhibitors

Corrosion inhibitors are chemicals that, when present in a system in relatively small quantities, produce a reaction with the metal surface resulting in a reduction in the rate or severity of corrosive attack. Inhibitors can interfere with either the anodic or cathodic reactions, can form a protective barrier on the metal surface against corrosive agents, or can work by a combination of these actions. For oil-field corrosion inhibitors, organic compounds containing nitrogen (amines) dominate because of their effectiveness under conditions of oil and water wetting, and their availability. Corrosion inhibitors usually contain three elements:

- One or more active inhibitor components
- A solvent base
- Certain additives, such as surfactants, dispersants, demulsifiers, and defoamers

Solvents are used to dilute inhibitors to control their physical characteristics (such as viscosity, vapor pressure, and pour point), to aid in obtaining proper inhibitor concentration and placement during treating, to assist inhibition, and to maintain a reasonable cost per unit volume (Ref 65).

Physical Characteristics of Inhibitors

Physical characteristics of inhibitors must be considered when evaluating a potential application. These include:

- Physical form
- Solubility and/or dispersability
- Emulsion-forming tendencies
- Thermal stability
- Compatibility with other chemicals

In modern offshore operations, it is particularly important to make sure that the corrosion inhibitors are compatible with other completion and workover fluids. Many times, these fluids are handled through the same control lines and pumped down to the sea bottom and through the wellhead or into subsea flow lines. Concerns for

incompatibility include: loss of inhibitor efficacy and formation of precipitates, emulsions, or gels that can plug the system.

Physical Form. Inhibitors may take either a solid or liquid form. Solid inhibitors have been made in the shape of a stick that will sink to the bottom of a well and then slowly dissolve and be drawn back with the produced oil and gas. These sticks are rarely used. Most corrosion inhibitors are in liquid form and have densities that range from 840 to 1440 g/L (7 to 12 lb/gal) (Ref 66). These liquids must not freeze when exposed to the coldest of field conditions and must be stable with a minimum loss to the vapor state when exposed to the hottest of field conditions.

Solubility/Dispersibility. The formation of an inhibitor film and its life are primarily governed by the solubility of that product in the system. There are three categories of solubility: soluble, insoluble, and dispersible.

A product is soluble in a fluid when it forms a clear mixture that does not separate. A product is insoluble in a fluid when it will separate after mixing to form an identifiable layer. Materials are dispersible in a fluid if they form a mixture that is not clear and separates slowly, if at all.

Different solubilities are required for different applications of corrosion inhibitors. An inhibitor to be added continuously to a waterflood should be water soluble or highly dispersible. Similarly, an inhibitor to be used for a squeeze treatment (e.g., where inhibitor and its carrier are squeezed into the formation under high pressure and then produced back) should be completely soluble in the carrying fluid to facilitate placement of the inhibitor without plugging the formation. On the other hand, where the only method of application is a periodic treatment, continuing protection requires some degree of insolubility of the inhibitor in the fluids to which it is exposed. In practical terms, this means that an inhibitor used in tubing displacement cannot be completely soluble in the well fluids. This is what gives the inhibitor its ability to remain for an extended period on the metal surface (i.e., referred to as its persistence on the metal surface). Also, a dispersion must be stable enough to remain intact until the inhibitor reaches the metal surface to be protected.

Emulsion-Forming Tendencies. Because of the chemical nature of most corrosion inhibitors, there is a positive tendency in water-oil systems to form emulsions. Some of these emulsions will break down quite readily under static or stratified flow conditions, while others are extremely stable and practically impossible to break. When squeezed into an oil or gas bearing reservoir, an incorrectly selected inhibitor can form an emulsion in the formation that blocks or severely restricts further production. Furthermore, a chemical inhibitor can also form an emulsion with produced water that is hard to "break" and that may complicate downstream separation of oil and water.

The inclusion of a demulsifier in a corrosion inhibitor is no guarantee against the formation of stable emulsions. Produced fluids from each field

must be tested to provide reasonable assurance that no stable emulsion will be formed upon application of a specific corrosion inhibitor.

Thermal Stability. Corrosion inhibitors generally have temperature limits above which they lose their effectiveness and change their chemical composition. This temperature may be variable for any one inhibitor, depending on such conditions as pressure and presence of water. A typical example is that of an acid-amine salt. Under atmospheric conditions, this salt will yield water and form an amide at 70 to 90 °C (160 to 190 °F). However, this chemical can be used in oil wells in the presence of water at these temperatures with no apparent degradation. Of course, exposure to high temperatures at low pressures will result in the vaporization of the solvent systems in these inhibitors and the formation of "gunk," a solid organic compound that can interfere with well production and related operations.

Compatibility with Other Chemicals. The compatibility of corrosion inhibitors with other chemicals is ordinarily not troublesome when the inhibitor and the other chemicals are present in parts per million concentrations. However, chemical users frequently want to mix various chemicals so that a single chemical pump can be used for injection. Many products are not compatible with corrosion inhibitors because of variations in solvent systems, type of chemicals (cationic versus anionic), and so on.

Most oil-field corrosion inhibitors are cationic to some extent; that is, they carry a positive electrical charge. Mixing a cationic inhibitor with an anionic chemical, such as a scale inhibitor or certain surfactants, will likely produce a reaction product that can have characteristics that are entirely different from those of either of its parent products. At best, the new material may function poorly; at worst, it may not function at all or may even form deposits in the system and plug control systems or even the well. When two or more chemicals must be used, this problem can be prevented by using separate injection points that are not closely spaced. It should probably be standard practice never to mix any two different products unless extensive compatibility and stability tests have been conducted in advance of the application. Depending on the situation, either product would avoid potential emulsion, solids precipitation, or fouling problems.

A final example of operating problems can be found where a conventional inhibitor is used in a gas stream upstream of a compressor. The non-volatile components in the inhibitor could be left behind to foul the valves of the compressor. This latter phenomenon is commonly referred to as "gunking."

Selection of Inhibitors

Many factors are involved in the selection of inhibitors, including:

- Identification of the problem to be solved and target corrosion rate requirements

- Corrosives present in the production environment (e.g., chloride, oxygen, CO₂, H₂S, sulfur, acids)
- Type of system (offshore or onshore, oil or gas or water or multiphase operations, etc.) that may influence the treatment method
- Pressure and temperature
- Production rates of oil, water, and/or gas
- Pipe sizes
- Production composition

Although problems such as rod breaks in pumped wells and leaks in gathering lines may initially be seen as purely corrosion failures, the actual cause of the problem could be oxygen, scale, or bacteria. Rod coupling failures could be caused by poor assembly or corrosion fatigue. Overstressing of rods greatly accelerates these failures. In such cases, mechanical measures could reduce or eliminate the need for chemical treatment. If attack is due to oxygen entry, installation of gas blankets or closing of the casing valve could greatly reduce corrosion.

The presence of corrosives such as H₂S and CO₂ greatly influences the choice of an inhibitor. Some inhibitors perform best in sweet fluids, while other inhibitors work best in sour fluids. Even the concentration of sodium chloride (NaCl) has a bearing on the choice of an inhibitor. With increasing NaCl content, some inhibitors will become insoluble and deposit. Table 5 shows the influence of corrosive type on inhibitor selection (Ref 67).

The type of system also has an effect on the selection of an inhibitor. The correct inhibitor to use is determined by whether the system is a pumping oil well, a gas-lift well, a gas well, a waterflood system, or a flow line. For example, a weighted inhibitor is seldom recommended in dry gas wells, because water is required to release the inhibitor before it becomes effective (Ref 68). Also, when a gas-lift well is treated, the

inhibitor is injected into the gas-lift lines. Therefore, the inhibitor must not have tendencies to form gunky deposits. The same is true if a capillary tube is being used for downhole inhibitor injection.

Both temperature and pressure have an influence on inhibitor selection. Bottom hole temperatures and pressures may get so high that inhibitors polymerize and form a sludge. Pressure influences the corrosivity of CO₂ and H₂S. The severity of corrosion increases with the partial pressures of these gases. Therefore, certain chemicals may work fine at one condition, but require an unacceptably high concentration to handle the same gas at higher pressure or temperature.

Velocity is yet another factor to consider. With pipelines, low velocity might be insufficient to displace water from low areas in the line. In the case of dry gas pipelines with low velocity, a water-soluble inhibitor should be selected and should be injected continuously. If the velocity is high enough to prevent any accumulations of water in low areas of a dry gas line, then an oil-soluble inhibitor should be batch treated. In addition to velocity, the rates of production of oil, gas, and water and the pipe size also determine the flow regime. As discussed previously in this article, certain flow conditions (e.g., slug flow and mist flow) can produce very high turbulence and wall shear stress on the surface of the pipe. Under these conditions, conventional chemical inhibitors that work well under less aggressive flow conditions often will not work under high shear conditions. Special inhibitor formulations that have been developed and that have high reaction rates and greater persistence under these conditions are required (Ref 69). Conversely, low flow conditions may result in stratified flow conditions where the oil and water phases separate. In this case, special consideration needs to be given to select oil-soluble

inhibitors that are also highly water-dispersible inhibitors that do not require extensive turbulence to achieve dispersibility.

The composition of the produced water also determines the choice of inhibitor. Criteria such as water/oil ratio, salinity of water, and acidity of the water and oil are vital to the correct selection of the inhibitor.

Commonly, tests are conducted in the laboratory using a standard wheel test where a corrosion coupon is exposed to a mixture of oil, water, and gas in small pressurized vessels with varying concentrations of inhibitors that are mixed by rotation. Although not infallible, this test attempts to duplicate field conditions and is credible for simple situations not involving high flow induced wall shear stress. Parameters such as temperature, water-cut, batch or continuous treatment, and whether the system is sweet or sour are reproduced as closely as possible to field conditions. Usually, these tests involve weight-loss coupons and can also involve use of electrochemical methods. ASTM G 170 provides guidance for basic inhibitor-screening procedures (Ref 70).

To develop more predictive tests, sometimes stirred autoclaves, flow loops, and jet-impingement devices are utilized to create certain test conditions that simultaneously have high H₂S/CO₂ partial pressure, concentrated brine, and high flow rate. Most importantly, it is crucial to have some basis to link the laboratory results and the field applications (Ref 71). This is where corrosion and flow modeling have also been utilized. The procedures for these tests often start with flow modeling of specific field production system under various production scenarios (high and low flow rate, high and low water production, etc.). This often involves examining many cases to define the worst-case conditions for water holdup and/or flow-induced wall shear stress and corrosion severity. These conditions can be then be simulated in the laboratory for evaluation purposes. The laboratory tests can be conducted under similar chemical conditions (production environment and dosage of inhibitor chemicals) while also controlling the wall shear stress to levels appropriate for the application.

The rate at which an inhibitor film is formed on a metal surface is completely dependent on the product formulation and the service environment. Generally, inhibitors that attain an effective surface film quickly operate better, particularly under flowing conditions. It can generally be said that film formation is a function of time and is not instantaneous. The concentration of inhibitor required to develop an adequate film is also directly related to the characteristics of the product, the severity of the corrosion, and the specific system parameters including temperature, pressure, and flow rate. Many factors affect the dosage and frequency of treatment, including:

- Severity of corrosion
- Total amount of various fluids produced (oil/gas/water)

Table 5 Influence of corrosion type on selection of inhibitor formulation type

Field designation (gas wells)	H ₂ S content, ppm	Inhibitor type(a)	General corrosion rate	
			mm/yr	mils/yr
A	0	N	0.190	7.5
		NPS	0.003	0.12

- Percentage of water (i.e., water cut in oil systems; water-to-gas ratio in gas systems)
- Nature and concentration of corrodents (H_2S , CO_2 , O_2 , etc.)
- Chemical type and formulation (inhibitor chemicals plus carrier fluid)
- Fluid level in the casing annulus

Because no laboratory test can take into account all of the conditions imposed by the oil well, the dosage and frequency of treatment must be constantly reviewed. Initially, the relative performance of inhibitors and their optimum dosage may be developed from laboratory screening tests. However, these recommendations may be changed based on prior experience in similar well conditions.

There are two general rules to follow for dosages. First, for continuous injection, a dosage of 10 to 20 ppm based on total produced fluid is used as a starting point. Second, for batch treatment, weekly batch frequency is used with a starting dosage of 3.8 L (1 gal) per week for each 100 barrels of daily fluid production.

Also, if the corrosivity of the system is known, the following general criteria can be used to define more accurately a treatment rate for continuous injection (Ref 72):

Severity of corrosion	Target inhibitor dosage
Mild corrosion	10–15 ppm
Moderate corrosion	15–25 ppm
Severe corrosion	>25 ppm

Several major problems can occur with inhibitors, including foaming, emulsions, scale removal and plugging, and safety and handling. Corrosion of other metals (e.g., stainless alloys, brasses, and copper-nickel alloys) as a result of exposure to corrosion inhibitors intended to work on steel can also be a problem in some applications.

The most appropriate action to take in avoiding difficulty from foaming is to determine where foam-forming conditions exist in the system. These will consist of places where the inhibitor-containing fluid is agitated with a gas, such as in a gas separator, a countercurrent stripper, or an aerator. The next step is to obtain a sample of the fluid and gas from the process step, add the inhibitor in question, adjust the temperature to that corresponding to the process step, and shake vigorously. If this test produces a stable foam, a potential problem exists. There are three potential remedies:

- An antifoaming agent can be added (this must be tested also).
- Tests can be conducted to select an inhibitor that does not cause foaming.
- The system can be shut down periodically and treated with a slug of persistent inhibitor.

The last two remedies are the least palatable because the need for an inhibitor is at hand and there are few processes that can be shut down with sufficient frequency to maintain effective inhibition by slug treatment.

Emulsions are another problem that can occur when the wrong inhibitor is used. The use of other chemicals, heat, or both can usually break these emulsions. A great variety of chemicals are used for this purpose, but no one material has proved effective for all emulsions. Therefore, some evaluation or testing is often required to select the correct chemicals.

A system can be plugged as the result of an inhibitor-loosening scale and suspending it in the fluid. This problem is best avoided by planning. The best preventive measure is to clean the system thoroughly, if possible, before inhibitor is applied. This can be with the use of scrapers, or pigs that can be passed through the system for removal. An alternative or supplementary method in systems that are very sensitive to suspended solids is to protect the sensitive parts with temporary filters.

As with most industrial chemicals handled in large volume on a regular basis, oil-field corrosion inhibitors should be treated with respect from a safety standpoint. These products contain complex formulations of highly reactive organic materials. While not always highly toxic (many acid corrosion inhibitor formulations are toxic), they can produce reactions because of the amines and aromatic solvents present. Reactions usually consist of skin burns from contact and dizziness from inhalation of the vapors. Field procedures that involve such practices should be eliminated or adequate safety precautions should be taken. Repeated contact with amines will cause the development of sensitization to these products in some individuals and potential long-term health problems. To avoid these problems, any contact with the body should be minimized through the use of safety equipment.

Another possible adverse effect of inhibition is an increased rate of corrosion of a metal in the system other than the one for which the inhibitor was selected to protect. For example, some amines protect steel admirably, but will severely attack copper and brass. Nitrites may attack lead and lead alloys, such as solder. It has also been reported that some amine inhibitor formulations can cause attack and deterioration of elastomeric seals (Ref 73) particularly at temperature commonly found in downhole environments. In some cases, inhibitors may react in the system to produce a harmful product. An illustration of this is the reduction of nitrate inhibitors to form ammonia, which causes SCC of copper and brass. The only way to avoid these problems is to know the metallic components of a system and to be thoroughly familiar with the properties of the inhibitor to be used.

Application of Inhibitors

Choosing the proper inhibitor for treating a corrosion problem in the oil field is important; however, it is equally important to select the correct treating method. The best inhibitor available will not successfully control corrosion

if it does not reach the trouble area. To be effective and economical, a corrosion inhibitor:

- Must be present at an initial concentration sufficient to promote complete coverage of all steel surfaces
- Must be replenished as necessary to repair and replenish the protective inhibitor film

Batch Treatments. These are commonly used in producing wells and, in some cases, in gas lines and crude flow lines (Fig. 17). Inhibitor can be batched down the tubing-casing annulus, through the tubing, or between pigs (in the case of a pipeline). The various types of batch treatment are:

- Standard batch
- Extended batch
- Annular slug
- Tubing displacement
- Between pigs batch

The limiting aspects of batch treatment are usually related to the severity of corrosion, the temperature of the system relative to the breakdown temperature for the active agents in the

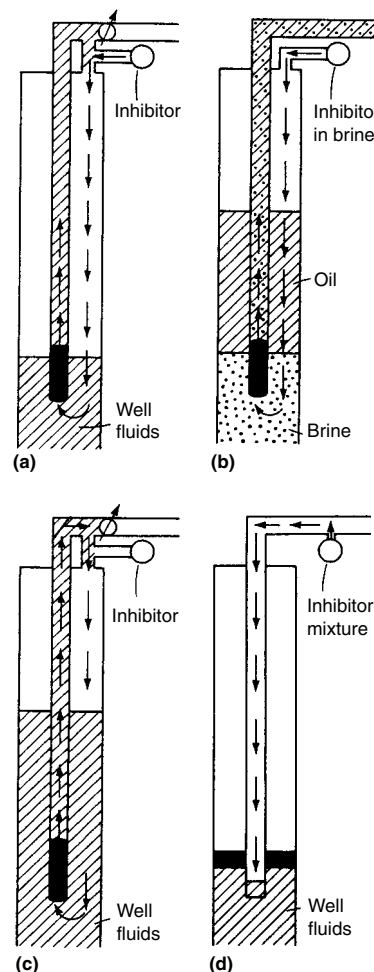

Fig. 17 Four types of batch inhibitor treating techniques. (a) Standard batch. (b) Annular slug. (c) Extended batch. (d) Tubing displacement

inhibitor, and the level of flow-induced wall shear stress. However, batch treatments can be both an effective and economically attractive method of inhibitor delivery for systems that are not overly aggressive, do not have excessively high wall shear stresses associated with the flow, or may not have the required equipment available for continuous inhibitor injection.

Standard Batch. This method is used for producing wells that are not equipped with packers. The inhibitor is put into the annulus, and the well is placed on circulation to distribute the inhibitor throughout the system. Normally, the longer the well is circulated, the better the inhibitor film. The application of this treatment in low fluid level wells depends on the fluid level maintained in the annulus. This method would not be recommended in wells that pump off. It would be estimated that a fluid level of at least 46 m (150 ft) should be maintained. In placing the treatment in operation in these wells, it would be recommended that the initial treatment be immediately displaced into the tubing and that a second batch of inhibitor be placed in the annulus.

Extended Batch. This method is a variation of the standard batch treatment, but in this case the inhibitor is left in the annulus. As the annular fluid level fluctuates, small amounts of inhibitor are carried in the oil into the tubing, thus giving the well periodic treatments weeks or months after the actual treatment. This type of treatment has lasted up to 6 months in some wells of Oklahoma (Ref 74). It must be remembered that this technique depends on a substantial fluid level in the annulus because the inhibitor is inventoried in the oil of the annular space.

Annular Slug. There is one technique for batch treating pumping wells that allows the well to continue full production while being treated. A water-dispersible or water-soluble inhibitor is mixed with water and placed in the annulus. This mixture will fall through the oil phase in the annulus. This technique will work if there is little or no water level in the annulus, but probably will not work if there is a substantial water level in the annulus. The frequency of treatment ranges from twice weekly to monthly.

Tubing Displacement. Wells that are set on packers or gas-lift wells are most commonly treated by tubing displacement. The inhibitor is either dispersed or put in solution in water or hydrocarbon carrier. The water may be fresh or produced. The hydrocarbon may be produced, or it may be a refined product, such as kerosene or diesel fuel. The inhibitor is usually used at about 10% concentration in the water or hydrocarbon. The desired amount of this mixture is then introduced into the tubing. If the well is a dry gas well, the mixture will fall to the bottom if sufficient shut-in time is given (from several hours to overnight, depending on the depth of the well). If the tubing contains liquids, the mixture must be displaced to the bottom of the well by pumping liquid (usually produced fluids) in behind the mixture. The amount of displacing liquid is calculated by determining the volume of

the tubing and subtracting the volume of inhibitor mixture. After the inhibitor has been displaced to the bottom, the well is usually shut in for 2 to 24 h. The well is then put into normal operation in the usual manner.

The tubing displacement technique is also known as a "kiss squeeze." This type of treatment will last from a week to several months, depending on the system and the inhibitor, and is normally used on flowing oil wells.

Between Pigs Batch. This method is used to control corrosion in gas pipelines and is only used by itself in moderately corrosive systems. The volume of inhibitor mixture needed to give a 3 mil thick coating can be calculated from an equation that takes into account the pipe diameter and length (Ref 75, 76). This technique can also be combined with scraper pigs to refurbish and protect older pipelines. It can remove the buildup of corrosion scale and deposits on the bottom of the pipeline and apply a protective inhibitor film. Pigging can also be used to manage and control water holdup at the same time applying a protective inhibitor film. The importance of these basic techniques is often overlooked in good corrosion control in oil and gas pipelines.

Continuous Treatment. This technique is used on producing wells, injection wells, pipelines, and flow lines. Continuous treatment simply involves introducing inhibitor on a continuous basis so that its concentration in the corrosive fluids is maintained at a level sufficient to prevent or reduce corrosion. This concentration may vary from a few parts per million to 50 ppm or more, depending on the severity of attack. There are many ways to continuously treat producing wells. The inhibitor can be injected into:

- A line that bypasses part of production into the annulus
- The power oil of a subsurface hydraulic pump
- A small string of tubing that runs down the production tubing (small-bore treating string)
- A small-diameter tubing "capillary" string that is installed external to the production tubing that goes down the annulus and attaches to a subsurface injection valve.

Squeeze Treatment. This is a combination batch-continuous method in which the inhibitor solution is placed into the formation. The inhibitor and diluent are displaced down the tubing and into formation by 25 to 75 drums of displacing fluid, which is usually clean crude, diesel fuel, or nitrogen. When the well is returned to production after a squeeze, the initial concentration of chemicals in the returned fluid is high and decreases very rapidly. The inhibitor continuously returns from the formation to repair any breaks in the inhibitor film. The second squeeze and successive treatments all give a longer treatment life than the first squeeze. Possibly, a portion of the chemical used in the first squeeze is trapped in the formation and cannot return to the well bore. This action is shown in Fig. 18 through use of iron counts. The advantages of squeeze treatment include:

- It can be used in tubingless or multiple completion wells.
- Treating frequency is reduced and ranges from 6 to 18 months, depending on the inhibitor, the formation, placement technique, and the fluids being produced.

The disadvantages of squeeze treatment are:

- High cost
- Possible clay swelling

Fig. 18 Iron content of produced water after squeeze treatment. Iron content is one measure of inhibitor effectiveness.

- Emulsion blocks that restrict production
- Injection pressure that must be kept below the pressure necessary to fracture the formation

This method is used on gas-lift wells having a high-pressure, a high gas-oil ratio, and a high rate of water production. More information on the selection and use of inhibitors in the oil patch is available in the article "Corrosion Inhibitors for Oil and Gas Production" in Volume 13A of the *ASM Handbook*.

Some guidelines for use of various treatment methods for oil and gas gathering systems are provided in Table 6. This table shows some of the variables that can influence selection of these techniques. These parameters include superficial gas velocity, ratio of liquid hydrocarbon to water, and chloride concentration in the water phase. In some cases, no chemical treatment is needed. In others, only pigging may be required. In most cases, the inhibitor method varies between batch and continuous. It should be noted that in many cases, pigging is an important part of the inhibition process. It helps to relieve water holdup by moving it through the system, and it also helps to distribute the inhibitor to all internal pipe surfaces (Ref 67).

Nonmetallic Materials

In recent years, there has been an increased use of nonmetallic materials in oil-field operations. These materials are being used because they generally do not corrode or suffer deterioration in the environments in which steel readily corrodes. They are also lightweight, suitable for rapid installation, and, in most cases, less expensive than steel. In a 1982 American Gas Association survey of 56 gas utility companies, it was found that nonmetallic pipe systems failed at only 13.2% the rate of metallic pipe systems when excavation damage is excluded (Ref 77). These data, however, allude to one of the major concerns for nonmetallics. Mechanical damage occurs because installers and maintenance personnel tend to handle them the same way they handle metallic material.

Types of Nonmetallic Materials Used

Nonmetallic pipe can be classified into three major categories: thermoplastic materials, fiber-reinforced materials, and cement-asbestos.

Thermoplastic materials can be repeatedly heated, softened, and reshaped without destruction. The most commonly used thermoplastic pipe materials are (Ref 58):

- Polyvinyl chloride (PVC)
- Chlorinated polyvinyl chloride (CPVC)
- Polyethylene (PE)
- Polyacetal (PA)
- Acrylonitrile-butadiene-styrene (ABS)
- Cellulose acetate butyrate (CAB)

Glass-fiber-reinforced thermoset materials are chemically set and cannot be softened or reshaped by the application of heat. There are two major classes of these materials in oil-field use:

- Fiberglass-reinforced epoxy (FRE)
- Fiberglass-reinforced polyester (FRP)

Cement-asbestos is the oldest nonmetallic material in use in the oil field. It is a combination of portland cement, asbestos fibers, and silica. It can be obtained with an epoxy lining, but most of this pipe currently in use is unlined (Ref 78). In recent years, efforts have been made to find substitutes for asbestos using portland cement, silica and various man-made fibrous materials, and chrysotile.

Joining Methods

The methods used to join various types of nonmetallic plastic pipe are shown in Table 7. The heat welding method uses a heating element to soften the ends of the joints, which are then pushed together and held until the joint cools. About 25% of all thermoplastic pipe joints are made by this method (Ref 58). Solvent welding can be used on some of the thermoplastic pipe materials and on both of the thermosetting materials. This method uses both a solvent and a glue to hold the joints together. Finally, threads can be used on all thermoplastic pipe materials.

The most common joint for cement-asbestos and other fibrous cement pipe products is the "slip joint." This kind of concrete pipe joint does not involve a coupling. There is a groove on the spigot end where a rubber gasket ring is placed. This gasket is compressed into the groove by the bell of the connecting pipe as they are pushed together, forming a watertight seal.

Advantages and Disadvantages

The **advantages** of nonmetallic materials include (Ref 58):

- They are generally immune to corrosion in aqueous systems.
- They are lightweight and are therefore easier to handle.
- Nonmetallic pipe is quickly joined and installed.
- No external protection, such as coatings or cathodic protection, is required.
- The smooth internal surface of nonmetallic pipe results in lower fluid friction loss.

Among the disadvantages of nonmetallic materials are (Ref 58):

- Nonmetallic pipe has a more limited working temperature and pressure. These limits are also more difficult to predict with assurance than the limits of steel pipe.
- Careful handling is required in loading, unloading, and installation.
- Nonmetallic pipe should be buried to protect it from sunlight, mechanical damage, freezing, and fire.
- Nonmetallic pipe has very low resistance to vibration and pressure surges.

Typical Applications

Thermoplastics have seen use in flow lines, gathering lines, saltwater disposal lines, liners for steel pipe in high-pressure operations, and fuel lines for gas engines. Polyvinyl chloride has a maximum temperature limit of 65 °C (150 °F) and a maximum operating hoop stress of

Table 6 Influence of production conditions and environment on selection of method for flow line inhibition

Condition(a)	Water cut <30%	Water cut >30%
Low Cl ⁻ /high velocity A < 10,000 mg/L V > 3 m/s	No treatment	Continuous inhibition
Low Cl ⁻ /low velocity A < 10,000 mg/L V < 3 m/s	Pigging	Pigging + continuous inhibition
High Cl ⁻ /high velocity A > 10,000 mg/L V > 3 m/s	Continuous inhibition	Continuous inhibition
Low Cl ⁻ /low velocity A > 10,000 mg/L V < 3 m/s	Pigging + continuous inhibition	Pigging + batch inhibition + continuous inhibition

27.5 MPa (4000 psi). Polyethylene has a maximum operating temperature of 40 °C (100 °F) and a maximum operating hoop stress of 4.3 MPa (625 psi) (Ref 54).

Glass-fiber-reinforced thermoset materials have also seen use in flow lines, gathering lines, saltwater disposal lines, liners for steel pipe in high-pressure operations, and fuel lines for gas engines. They have also been used for tubing in disposal and injection wells. Neither FRE nor FRP should be used for a well production flow line or gas-gathering system at pressures above 2.1 MPa (300 psi) and temperatures of 65 °C (150 °F). These materials should not be used in vacuum systems or where repetitive vacuum surges are likely to occur and in lines handling sand-laden fluid.

In addition, FRP has been used for stock tanks and barrels ranging in size from small chemical tanks of 1890 L (500 gal) or less to larger tanks of 104,000 L (27,500 gal) or larger. Even sucker rods used in pumped oil wells have been made of FRP.

Cement-asbestos and other cement fibrous materials have been used in low-pressure saltwater disposal lines. They have a maximum temperature rating of 95 °C (200 °F).

Specifications

There are several specifications provided by API that provide guidance on design, use, and handling of plastic and reinforced tubulars and components in oil-field applications:

- 15HR, "High Pressure Fiberglass Line Pipe," 2nd ed., April 1, 1995
- 15LE, "Polyethylene (PE) Line Pipe," 3rd ed., April 1, 1995
- 15LR, "Low Pressure Fiberglass Line Pipe," 6th ed., Sept 1, 1990 (ANSI/API Spec 15LR-1992)
- 15LT, "PVC Lined Steel Tubular Goods," 1st ed., Jan 1, 1993
- RP 5L2, "Internal Coating of Line Pipe for Non-Corrosive Gas Transmission Service," 3rd ed., May 31, 1987 (ANSI/API RP 5L2-1992)
- RP 15 TL4, "Care and Use of Fiberglass Tubulars," 1st ed., Oct 1, 1993

Environmental Control

Oxygen dissolved in oil-field water is one of the primary causes of corrosion. Dissolved oxygen is needed at 25 °C (75 °F) for an appreciable corrosion rate in neutral waters, while even in high-salinity brines at 150 °C (300 °F), the corrosion rate is low once the oxygen is removed (Ref 56). This type of corrosion is usually a localized form of attack, such as pitting, rather than a uniform attack. Oxygen also causes the growth of aerobic bacteria, algae, and slime, which can create plugging and enhance pitting. Also, mixing an oxygen-

containing water with oil-field waters containing dissolved iron or hydrogen sulfide can cause precipitation of iron oxides, iron hydroxides, or free sulfur, thus causing serious plugging problems. In one case, some injection wells of a waterflood in west Texas were filled with as much as 23 m (75 ft) of iron hydroxides after a few months of service (Ref 79). Even if there are other corrosive agents present, air-free operation is needed in order for film-forming corrosion inhibitors to work (Ref 80); the presence of dissolved oxygen will significantly reduce the effectiveness of corrosion inhibitors unless specific multifunctional chemical formulations are utilized.

Both mechanical and chemical means have been used to remove dissolved oxygen from oil-field waters. The mechanical means are countercurrent gas stripping and vacuum deaeration, while the chemical means include sodium sulfite, ammonium bisulfite, and sulfur dioxide. The choice of oxygen-removal method depends on economics. Usually, mechanical means are used when large quantities of oxygen are to be removed. Chemical removal is usually employed to remove small quantities of oxygen and even sometimes for the removal of residual oxygen after the mechanical means have been used.

Care must also be used to minimize air contamination of injected fluids such as corrosion and scale inhibitors, biocides, hydrate, and wax control fluids. Aeration of these fluids can lead to a source of oxygen contamination and resultant corrosion in production environments downstream from the point of injection. In many cases, storage tanks for injected fluids need to use an inert cover gas, which can range from nitrogen, to carbon dioxide, to produced gas. It should be noted that if water or brine is present, the use of carbon dioxide as a cover gas may result in the formation of an acidic media that can sustain corrosion on its own part. Additionally, many organic solvents such as glycol, methanol, and ethanol have much higher oxygen solubility than is common for aqueous solutions. For example, dissolved oxygen concentrations in ethanol from air saturation are in excess of 50 ppm versus 4 to 6 ppm for water and brine. This can lead to oxygen corrosion problems when such aerated fluids are injected into the production environment. Often the physical manifestation of oxygen corrosion is unexpectedly high rates of corrosion and/or the presence of pitting and crevice corrosion.

Mechanical Methods

Gas stripping is performed in either a packed column or a perforated tray column. Perforated tray columns are preferred because they are not as easily fouled with suspended solids or bacterial slime as packed columns. Figure 19 illustrates a tray-type gas stripping column. Oxygenated water flows into the top of the column, while the stripping gas flows through the bottom inlet. As the gas bubbles up through the

water, oxygen comes out of solution. The trays or packing in the column increases the contact area. These systems are designed to use not more than 0.06 m³ (2 ft³) of gas per barrel of water being stripped (Ref 54). The gas source should be free of both oxygen and H₂S. Either natural gas or scrubbed exhaust gas from engines is commonly used. The principle of removal is to reduce the concentration of oxygen in the gas coming in with the water by dilution with the stripping gas.

Vacuum Deaeration. In this process, a vacuum is created in a packed tower, and as the oxygenated water is passed over the packing, the low pressure causes the oxygen to bubble from solution. The vacuum pump pulls the oxygen, water vapor, and other gases from the top of the tower. The tower usually consists of several different pressure stages, as shown in Fig. 20. In a packed column, each stage consists of a height of packing, which is sealed from the stage below by a layer of water in the bottom of the packing (Ref 57). A single-stage tower will economically remove oxygen only to a lower limit of about 0.1 ppm (1000 ppb) because the excessive vacuum pump horsepower required to achieve lower concentrations is not usually feasible. Therefore, multistage columns are needed. Dissolved oxygen concentrations as low as 0.01 ppm (10 ppb) have been achieved in three-stage towers (Ref 57). While this level of

Fig. 19 Tray-type countercurrent gas stripping column. Source: Ref 57

deaeration will improve operations and reduce corrosivity over fully aerated conditions, this level of residual oxygen is still marginal in terms of oxygen corrosion. Added gains are possible with a further reduction in corrosivity and pitting susceptibility with the use of additional deaeration methods.

Combination Vacuum Deaeration and Gas Stripping. Vacuum deaeration, with the use of 0.003 m^3 (0.1 ft^3) of natural gas, has been used to reduce the oxygen content of water from 5 to 0.05 ppm (5000 to 50 ppb) or less in a 40,000 barrel/day waterflood in west Texas. Single-stage vacuum deaeration reduced the oxygen content of the water to 0.17 ppm (170 ppb), while the gas stripping further reduced the oxygen content to 0.05 ppm (50 ppb). Corrosion rates in the water were reduced from 0.36 to 0.04 mm/yr (14 to 1.6 mils/yr) (Ref 81, 82).

Chemical Methods

Sodium sulfite is used to scavenge oxygen from water and is available as a liquid or as a powder. It reacts with oxygen:

Approximately 8 ppm of Na_2SO_3 is required to react with 1 ppm O_2 . A 10% excess is usually required for complete reaction, and a catalyst such as cobalt chloride (0.1 ppm) is needed to scavenge to acceptable levels within a few minutes. Because Na_2SO_3 solutions will react with atmospheric oxygen, an inert gas blanket is required on the storage tank.

Ammonium bisulfite is a liquid scavenger and reacts with oxygen:

An 80% solution of NH_4HSO_3 requires a 10-to-1 ratio by weight for the reaction. A 10% excess is needed to complete the reaction. Ammonium bisulfite does not react with air and can be stored in open containers. A catalyst is not usually needed for oil-field brines. Because the chemical is supplied as a solution with a pH of 4 to 4.5, it must be stored in a corrosion-resistant vessel. Type 304 stainless steel is commonly used (Ref 57).

Sulfur dioxide is a chemical scavenger that can be either supplied as a liquified gas under pressure in a cylinder or generated by burning sulfur. The reaction between sulfur dioxide and oxygen proceeds according to:

A quantity of 4 ppm by weight of SO_2 is required to remove 1 ppm of oxygen. A 10% excess and a catalyst such as cobalt chloride are needed to complete the reaction. Sulfur dioxide from cylinders is applied by using a bypass line that handles approximately 10% of the total fluids, as shown in Fig. 21. The scavenger is added to the bypass fluids. The materials used in this bypass line should be resistant to acid attack because of the low pH formed from the reaction. Use of SO_2 cylinders is most advantageous in small systems (less than 10,000 barrels per day) or where small concentrations of dissolved oxygen are encountered in larger systems (Ref 83).

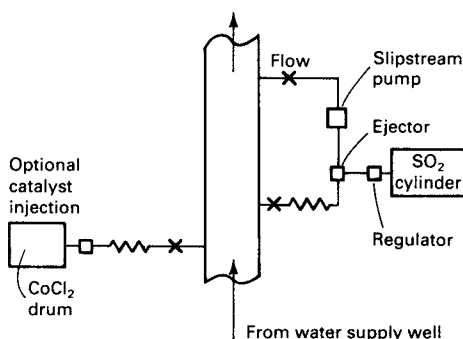

Fig. 21 Application of SO_2 through the use of a bypass line.

When larger volumes of water are to be treated, it may be more economical to produce SO_2 gas by burning sulfur. This gas is then dissolved in a sidestream of the water to be treated, pumped through the packed column, and then back into the main line.

Precautions

Some precautions involving oxygen scavengers should be noted (Ref 57):

- Oxygen scavengers will react with chlorine and hypochlorite (ClO^-), which are added to injection water for bacterial control. Therefore, these chemicals should be added downstream of the point of scavenger injection to allow completion of the scavenger-oxygen reaction.
- Any organic chemicals, such as biocides, scale inhibitors, and corrosion inhibitors, can possibly interfere with the scavenger-oxygen reaction and should be selected with care.
- Oxygen scavengers cannot normally be used in sour systems. If H_2S is present, it may react with the cobalt chloride catalyst to form insoluble sulfides (Ref 57).
- The reaction rates for oxygen scavengers can be a function of fluid temperature, and at low temperatures these reaction rates can be slow. Therefore, at cold temperatures common in locations such as the North Sea, Canada, and Alaska, and in deep water subsea operations, selection of deaeration chemicals is critical and adequate residence time for complete reaction needs to be considered.

Oxygen Exclusion

It is usually more economical to exclude oxygen from oil-field equipment than to remove it after it has entered the system. The most common means of excluding oxygen is through the use of gas blankets on water supply wells and water storage tanks. Maintenance of valve stems and pump packing is also important. In water-handling systems, a leaky valve can be a source of oxygen contamination into the system through backstreaming of oxygen counter to the direction of the leak.

All tanks handling air-free water should be blanketed with an oxygen-free gas such as natural gas or nitrogen. Most tanks require only a few ounces of pressure over atmospheric (Ref 80). The regulator should be sized to supply gas at a rate adequate to maintain pressure when the fluid level drops. In some processes, combustion gas is used to "inert" tanks. This type of gas has the ability to exclude air if kept at a positive pressure relative to atmospheric. However, it often contains high concentrations of carbon dioxide and may still contain several mole percent oxygen. As long as the environment is basically dry, combustion gas can be useful to reduce some of the ill effects of aeration. However, under hydrated conditions, the carbon

dioxide in the gas can be dissolved in entrained or precipitated water phases that will increase the corrosivity to materials of construction.

Oil blankets should not be used in place of gas blankets. Oxygen may be 5 to 25 times as soluble in hydrocarbons as in oil-field waters (Ref 80). Oil blankets will coat precipitates in the water, which can lead to well plugging problems. Some bacteria will even thrive at the oil/water interface (Ref 57).

Even supply wells and producing wells may need to be gas blanketed to prevent oxygen entry. If these wells are operated cyclically without gas blankets, oxygenated air will be drawn into the annulus every time the well is turned on and the fluid level drops. Oxygen can also enter a pump on its suction side if a net positive suction head is not maintained. If the seals start to leak, air can then be sucked into the pump (Ref 80).

Problems Encountered and Protective Measures

The problems encountered and protective measures discussed in this section are based on the state-of-the-art as practiced daily by corrosion and petroleum engineers and production personnel. These are by no means all of the methods employed for corrosion protection, but they represent the most commonly used processes.

Drilling Fluid Corrosion

Due to the nature of drilling conditions, corrosion is a problem in water-based drilling fluids. Important considerations are the causes of corrosion and the rate and forms of corrosion attack.

Causes of Corrosion

The major environmental causes of corrosion in drilling fluids are oxygen, carbon dioxide, hydrogen sulfide, ionic concentration, and low pH. Physical conditions causing corrosion include metal composition, metal properties, string design, stress, and temperature. Combined physicochemical corrosion accelerators include stress corrosion and erosion-corrosion. Micro-organisms also introduce biological causes of corrosion in drilling environments.

Combined Effects. The forms of corrosive attack will provide characteristic patterns that can be identified and used in selecting preventive methods (Ref 84). The major forms of attack are general corrosion, pitting, crevice corrosion under deposits, corrosion fatigue, and SCC. Erosion-corrosion, uniform attack, and galvanic corrosion are also common problems. More than one form of attack can occur, and one form can transform into a second form. For example, a pit can deepen and increase stress, initiating stress corrosion or fatigue (Table 8).

Failure Analysis

Analysis of used and failed equipment can provide a means of developing corrosion prevention methods (see the article "Analysis and Prevention of Corrosion-Related Failures" in *Failure Analysis and Prevention*, Volume 11 of the *ASM Handbook*. Identification of corrosion products (Ref 85) and corrosion forms (Ref 33, 86) can be developed into cause-effect mechanisms.

Monitoring

Drill pipe corrosion coupons are used to measure the rate, form, and cause of corrosion (Ref 87). Corrosion rates of 2.4 to 9.8 kg/m²·yr

(0.5 to 2 lb/ft²·yr) free of pitting is an acceptable range. The lower rate should be used as a baseline estimate for deviated holes, deep drilling, and/or high-stress conditions; however, local conditions and lack of appropriate anticorrosion measures being taken can result in substantial increases in corrosivity. Special monitoring using linear polarization (Ref 88) or galvanic probes (Ref 89) will provide instant detection of corrosion and changes in rates that can be related to system conditions on a real-time basis. However, in most cases, corrosion monitoring of drilling fluids is simply not conducted since it is not specified by the operator or contractor. Figure 22 shows changes in corrosivity produced in drilling fluids as a result of changes in conditions such as flow rate, which can be identified when real-time monitoring is used. The most appropriate locations for corrosion monitoring of drilling fluids are (a) the return line to the mud pit since an influx of corrosive gases downhole may decrease fluid pH and increase corrosivity, or (b) in the mud pit and/or its outlet line going to the well, if concerns for oxygen scavenging and initial pH control are of interest. These two locations provide convenient information on which to control the corrosivity of drilling fluids (Ref 90).

On-site chemical and physical analyses of drilling fluid properties are conducted on a frequent basis (Ref 87). Test procedures should include oxygen, CO₂, H₂S, and bacterial analysis for comprehensive monitoring of corrosion problems. The *Drilling Manual*, 11th ed. (CD-ROM), published by the International Association of Drilling Contractors, presents equipment inspection methods as well as information on the care, handling, and specifications of tool joints, drill pipe, casing, and tubing. Reference is made to this manual to provide comprehensive information on drilling and production equipment.

Table 8 Drilling fluid corrosion control troubleshooting chart

Corrosion cause	Primary source	Identification	Major corrosion forms	Remedies
Oxygen	Atmosphere, mud conditioning, equipment, oxidizing agents, air drilling	Oxygen test, iron oxide by-products	Underdeposit corrosion, pitting	Avoid mechanical air entrapment in mud pits or foamers; use oxygen scavengers for normal drilling; use passivating agents for air drilling operations.
Hydrogen sulfide	Formation, bacteria, chemical or thermal degradation	H ₂ S analysis, iron sulfide test	Underdeposit corrosion, uniform corrosion, sulfide stress cracking	Control pH ≥ 9.5; use sulfide scavengers or filming inhibitors, reduce stress; change to oil mud in severe H ₂ S environments.
Carbon dioxide	Formation, bacteria, chemical or thermal degradation	CO ₂ analysis, iron carbonate by-products	Underdeposit corrosion, pitting	Control pH ≥ 9.5; use calcium hydroxide to combine with and precipitate CO ₂ products; use filming inhibitors.
Dissolved salts	Formation, chemical additives	Water analysis	Underdeposit corrosion, uniform corrosion, chloride SCC	Control pH ≥ 9.5; remove oxygen, H ₂ S, and/or CO ₂ ; use filming inhibitors.
Bacteria	Makeup water, formation	Culture tests for sulfate-reducing bacteria and/or slime forms	Underdeposit corrosion, sulfide stress cracking	Control pH ≥ 9.5; add biocides.
Temperature	Formation heat, friction	Test	Sulfide stress cracking, pitting	Select temperature-stable chemicals; use friction/torque reducers; cool mud; use oil mud.
Abrasion (erosion-corrosion)	Formation, directional or deviated hole	Observation	Erosion-corrosion	Use lubricants, torque reducers, and filming inhibitors; control solids; use oil muds.
Metal composition				
Carbon steels, ≤ 22 HRC	Underdeposit corrosion, uniform corrosion, pitting	Control pH ≥ 9.5; control oxygen, H ₂ S, and CO ₂ ; limit stress.
Carbon steels, > 22 HRC	Underdeposit corrosion, sulfide stress cracking, pitting	Control H ₂ S to very low levels.
Stainless alloys	Chloride SCC	Limit salts and temperature exposure; control deposits.
Aluminum alloys	Underdeposit corrosion, galvanic corrosion, pitting	Limit pH to 9.5–10.5; use passivation.

Oxygen Corrosion Control

Oxygen can cause pitting corrosion of steel and stainless alloys and crevice corrosion under deposits and is considered to be the most serious corrosion accelerator in drilling environments. Oxygen enters the drilling fluid system externally from the atmosphere, usually by way of solids-control and mud-mixing equipment (Ref 91). The operation of this equipment to reduce air entrapment into the circulating system is an effective technique for limiting oxygen levels. Foaming problems are characteristic of some mud systems and can result in high oxygen levels on the high-pressure side of the pump. Defoaming the fluid or maintaining properties to release gas quickly is required to overcome this problem.

Oxygen scavengers, such as sodium sulfite or ammonium bisulfite, are used to remove oxygen from drilling fluid (see the discussion "Environmental Control" in this article). Treatment methods involve a continuous addition of chemical at the rate of 10 mg/L sulfite ion for each 1 mg/L of oxygen present in the fluid. A residual sulfite concentration of approximately 100 mg/L is maintained in the drilling fluid as a functional means of controlling oxygen in drilling systems. Oxygen scavenger catalysts are frequently required to overcome interfering side reactions that prevent the oxygen-sulfite reaction. Calcium in the fluid can combine with sodium sulfite and form calcium sulfite precipitate, thus preventing the sulfite ion from scavenging oxygen. Aldehydes and chlorine dioxide used as biocides in drilling fluids react with sulfite ions and may prevent oxygen removal. The addition of cobalt or nickel catalysts overcomes many of these problems by increasing oxygen-sulfite reaction rates.

Passivating compounds, such as sodium nitrite, are used to protect equipment during air, mist, or foam drilling operations. For decades chromates were used, but these components have been banned in nearly all cases as a result of their

known carcinogenic nature. Treatment levels range from approximately 500 to 2000 mg/L of nitrite ion in fresh to slightly brackish fluid. Higher concentrations are required in high-brine solutions, and sodium nitrite is not recommended above approximately 25,000 mg/L of chloride ion concentration. A noteworthy disadvantage of using passivating agents is the tendency toward accelerated pitting attack if treatment levels are too low or if deposits exist under which the metal cannot be passivated. Zinc compounds are often combined with passivating agents to reduce pitting tendencies. Treatments for controlling deposits are recommended to mitigate underdeposit attack and are covered in the discussion "Scale and Deposit Control" in this section. Nitrite compounds are not compatible with sulfite-type oxygen scavengers.

A clear advantage is gained in the use of sodium nitrite when hydrogen sulfide is encountered in the well. These compounds oxidize and remove H_2S (see the discussion "Hydrogen Sulfide Corrosion Control" in this section).

Atmospheric corrosion occurs on drilling equipment in urban, polluted, tropical, and marine environments. Protective coatings are commonly applied at the steel mill or storage yard and periodically between drilling operations. Many coating compositions are commercially available for both short- and long-term storage (2 or 3 years). The filming or waxy materials containing inhibitors that are typically used during drilling often provide good atmospheric protection for short periods between jobs. For long-term exposure, careful rinsing with fresh water, surface cleaning, and a selected atmospheric coating are recommended.

Hydrogen Sulfide Corrosion Control

Hydrogen sulfide causes three forms of corrosive surface attack—underdeposit (crevice) corrosion, pitting, and sulfide stress cracking.

Corrosion control methods include selecting corrosion-resistant materials (stainless steels and nickel-base alloys), removing the H_2S from the fluid, use of chemical inhibitors, and reducing stress. Hydrogen sulfide enters the drilling fluid primarily from the formation, but it can also come from thermally degraded mud products, sulfate-reducing bacteria, and makeup water.

Alkaline pH control ($>pH 10$) and sulfide scavengers are used to neutralize, precipitate, and/or oxidize H_2S . Film-forming amine-type inhibitors are recommended for coating the drill string. Caustic soda or calcium hydroxide treatments are used to neutralize the acid gas. Alkaline pH above 10 results in the production of sodium bisulfide or sodium sulfide products that are almost totally water soluble. This treatment provides both personnel safety and corrosion protection. A side benefit of maintaining high pH in drilling fluids is the natural passivation effect it provides against corrosion through the formation of a hydrated iron oxide on the steel surface.

Compounds of iron oxide (Fe_3O_4), zinc carbonate, zinc oxide, zinc chelates, and copper are used to precipitate sulfide ions from solution. Pretreatments of approximately 1 kg/barrel (2 lb/barrel) of one of the scavengers are commonly recommended as a precaution against a small influx of H_2S entering the mud system and causing damage. Tests are used to monitor scavenger concentrations and treatment requirements. Chemicals such as sodium nitrite compounds are used to oxidize H_2S to sulfate or elemental sulfur. The oxidizing process is a fast and efficient method of removing H_2S from the system. There is no compatibility problem with the sulfide scavengers listed previously. Formaldehyde and chlorine dioxide are compounds that are frequently used as drilling fluid biocides. These products react with hydrogen sulfide, offsetting its corrosive action; however, their biocidal properties are diminished or eliminated in the process.

Filming amine inhibitors provide protection from H_2S surface attack and hydrogen embrittlement. Oil-soluble filming inhibitors applied directly on the drill pipe are recommended to offset corrosion fatigue and hydrogen embrittlement. Care should be taken with cationic filming inhibitors, which can damage mud properties by flocculating the anionic clays in drilling systems. Oil muds provide the most effective protection against all corrosion causes, including H_2S . The oil phase provides a non-conductive film covering exposed equipment and thus preventing the corrosion process.

Stress reduction by mechanical changes, such as rotary speed and less weight on the bit, is effective in reducing H_2S -induced embrittlement or cracking failures. Torque-reducing agents, particularly in high-angle drilling, are effective in lowering stress as well.

Material selection for drill pipe and casing can have a significant effect in controlling sulfide stress cracking. The brittle failures related to H_2S are linked to the hardness and yield strength of the steel resulting from metallurgical processing.

Fig. 22 Monitoring of corrosion in drilling fluids versus flow conditions. LPR, linear polarization resistance; Pitting Factor values, defined as the standard deviation of the corrosion current divided by the mean corrosion current, ≥ 0.1 indicate active pitting conditions.

As a general rule, steels with hardness levels below 22 HRC or with maximum yield strengths of 620 MPa (90 ksi) have few sulfide stress cracking problems. Modern developments in steelmaking and tube-making technologies have resulted in an increase in this limiting hardness to between 26 and 30 HRC (depending on the steel composition, processing, and microstructure) while maintaining resistance to sulfide stress cracking. This comes through selection of chromium-molybdenum steels, microalloying additions, and ID/OD quenching procedures that produce a uniform martensitic structure in the steel upon quenching and which can subsequently be tempered at the highest temperature possible while maintaining minimum strength properties after processing. Cold work, such as tong or slip marks, increases the hardness of steel, and sulfide stress cracking then becomes a problem. The service stresses in drilling frequently demand materials of great strength, requiring hardness and strength levels that are susceptible to sulfide stress cracking. Because of such requirements, the primary means of avoiding sulfide stress cracking is by control of the drilling fluid. A full discussion of the metals used in H₂S environments is provided in NACE MR0175/ISO 15156 (Ref 14).

Higher temperatures (above 80 °C, or 175 °F) reduce susceptibility to sulfide stress cracking of high-strength steel. This factor can become advantageous in drilling and production operations if properly controlled. For example, an influx of H₂S while drilling may not cause damage if the fluid temperature is above 80 °C (175 °F) in the hole. If H₂S is detected, scavenging should always be completed before operations are begun that would lower the metal temperature, such as pulling the drill pipe from the hole.

Carbon Dioxide Corrosion Control

Carbon dioxide causes localized corrosion primarily through its solubility in aqueous fluids and its role as an "acid" gas in reducing pH. It can also combine synergistically with velocity to produce a localized corrosion mechanism referred to as mesa corrosion whereby filmed and nonfilmed regions of a steel surface can corrode at drastically different rates. In combination with chloride salts, carbon dioxide can also induce general or pitting corrosion. Corrosion control methods involve controlling the pH in the higher alkaline ranges (an influx of CO₂ will tend to reduce pH). An effective technique is to treat the mud with calcium hydroxide to neutralize this acid-forming gas and to precipitate carbonates, thus lowering CO₂ levels. Film-forming inhibitors of the oil-soluble amine type applied by spraying the outside of the drill pipe and batch treatments for inside diameter filming are recommended to penetrate pits and deposits, stopping their corrosion action. Control of CO₂ is quite similar to H₂S corrosion control, and these two gases often enter the mud from the formation together.

Scale and Deposit Control

Mineral scale, corrosion by-products, and drilling mud solids that form deposits on exposed metal are a major factor in setting up conditions that result in underdeposit pitting attack. The prevention and removal of these deposits with scale inhibitors is quite effective in offsetting most serious drilling fluid corrosion problems. Inhibitors such as organic phosphonate, phosphate esters, and others of the acrylic, acrylamide, or maleic acid base structures have been effective. Products that exhibit threshold effects, temperature stability, and strong surface-active characteristics are useful. Treatments are variable because of environmental conditions, which differ greatly in drilling fluid compositions. As general rules apply, scale control treatments of 15 to 75 mg/L are used on a daily basis for most mineral-scale control situations. Treatments above this level are used to control deposits of metal corrosion by-products. Considerably higher treatment levels, up to 1000 mg/L, are used to provide corrosion protection. Care should be exercised in using the higher treatment levels, because these compounds may alter mud properties because of their dispersing characteristics.

Oil Production

There are two main types of producing oil wells: artificial lift wells and flowing wells. Artificial lift wells can be further divided according to the method used to pump the hydrocarbon to the surface. These include rod-pumped wells, wells that use downhole hydraulic pumps, and gas-lift wells. Approximately 90% of the artificial lift wells in the United States are rod pumped.

Artificial Lift Wells

Rod-Pumped Wells. In a rod-pumped well, the potential for corrosion damage is aggravated by the sucker rods alternately being stretched and compressed and by the abrasion of the rod couplings on the inside of the tubing. It is common for a well to have continuing sucker rod failures. Pulling and replacing the rods is a quick fix, but the problem will continue to exist until the root cause of the failure is identified and corrected. Identifying the problem is the most important step, because corrective action cannot be taken if the cause is not clear. Rod breaks should be inspected immediately after the rod string is pulled to determine if corrosion is occurring and to determine the steps that can be taken immediately to prevent a recurrence.

Corrosion in rod-pumped wells can be caused by several mechanisms, as discussed below (Ref 92). Galvanic corrosion is caused by dissimilar metals in contact or by the difference in metallurgy or metallurgical condition between two areas on a sucker rod. Most galvanic corro-

sion on rods is caused by differences in metal condition caused by hammer, wrench, or tong marks and the grooves left by rod-straightening machines. The impact area will be cathodic to the body of the rod, and corrosion will occur adjacent to the mark. Sucker rods have a soft decarburized layer or skin of low-carbon steel 0.13 to 0.2 mm (5 to 8 mils) thick. This layer can be broken by careless handling. Anodic regions produced by surface wear can also show preferential corrosion relative to properly filmed (cathodic) regions.

Bent rods are sometimes straightened and used again. This is poor practice, because a bent rod is permanently damaged, contains local plastic deformation and residual stresses, and should be discarded. A rod-straightening machine can put spiral grooves around the rod, and corrosion will occur directly adjacent to the groove.

Any of these conditions will lead to localized corrosion and pitting, and stress raisers will be set up. The cyclic stresses resulting from alternately stretching and compressing the rods during pumping operations will lead to rapid failure at these sites of stress concentration.

Stray current from surface equipment or leakage from a cathodic protection system will cause severe corrosion where the current leaves the rod string. It is usually seen on couplings or the part of the rod that is close to the coupling.

Damage from oxygen corrosion may take place when the rods are stored outdoors or when oxygen enters the wellbore through the annulus. This later becomes a common problem where rod packings are worn or where oxygen enters the annulus of the well during pumping. Rusting of stored rods will often cause pitting, and rust deposits can set up concentration cells or underdeposit corrosion when the rods are run in the hole. Oxygen can enter into the wellbore in wells that pump off. Oxygen can also be introduced during inhibitor-treating operations. This will aggravate other forms of corrosion by depolarizing the cathodes on the metal surface during the corrosion reaction and accelerate local anodic attack. Oxygen corrosion generally occurs in the lower part of the well: the casing, pump, tubing, and the lower part of the rod string. The effect lessens in the upper part of the well, because the oxygen is depleted by the corrosion reaction.

Carbon dioxide or sweet corrosion is caused by CO₂ from produced gases dissolving in water and forming carbonic acid. A low pH results, and the carbonic acid will react directly with the steel rod and cause metal loss and pitting. The pits formed are usually round bottomed with sharp sides, and they may be connected in a line or will sometimes form a ring around the rod. Fatigue cracks will be initiated at the bottom of the pits.

Carbon dioxide corrosion is aggravated by the presence of oxygen and organic acids. Oxygen depolarizes the cathodes, and organic acids fortify the low pH condition. This can remove normally protective carbonate scale. The

formation of iron carbonate scale is the major limiting factor in CO₂ corrosion. The tendency for scale formation increases with increasing pH and temperature. Therefore, CO₂ corrosion is normally observed at low to intermediate temperatures. Many pumping wells are in the temperature range (<100 °C, or 212 °F) that is most conducive to CO₂ corrosion and pitting. At these temperatures, the iron carbonate scale is formed mainly away from the surface, with some forming as a discontinuous layer. Accelerated metal loss occurs in the gaps in the scale layer, and pits or mesalike features are formed.

Carbon dioxide corrosion may be sudden and catastrophic when breakthrough takes place in CO₂ floods. Wells that have been noncorrosive have failed within weeks after breakthrough. This is caused by the increase in acidity of the well fluids. In water-alternate-gas (WAG) CO₂ floods, breakthrough also brings a significant increase in water content in the production.

Hydrogen sulfide ionizes in water to form HS⁻ and hydrogen ions. Hydrogen sulfide corrosion is characterized by metal loss and pitting and can be quite severe particularly in presence of high levels of chlorides in the fluid. Iron sulfide formed on the steel surface generally does not form a protective layer having a powdery appearance and feel. Being a conductive material, the sulfide film is usually cathodic to the metal surface. Even if a protective sulfide layer is formed (generally at higher pH levels), a break in this layer will result in a galvanic couple with the filmed region resulting in a high probability for pitting.

The presence of oxygen will increase the corrosion rate in sour (H₂S) systems, and oxygen, in addition to depolarizing the cathodes, reacts with iron sulfide and forms elemental sulfur. This disturbs or removes the sulfide layer and results in an increase in the corrosion rate. Elemental sulfur is also corrosive to steel, which further increases the corrosion rate.

Organic acids increase the corrosion rate by making the iron sulfide scale less protective, thus exposing the bare steel surface. This comes about by lowering the pH and increasing the driving force of the corrosion reaction. At pH less than 6, H₂S reacts directly with the metal, and little or no protective iron sulfide is formed on the surface.

The pits formed during H₂S corrosion are generally small, round, and cone shaped. The acute angle at the bottom of the pit is a stress raiser, and it leads to cracking. Pits are usually not connected and are in a random pattern.

The amount of H₂S present has a direct effect on the time to failure of rods due to cracking. In some cases, corrosion pits are so small as to be undetectable before cracking occurs, or cracking may take place quickly at dents or nicks on the rods. However, these all become very critical in service life with conditions that contain increasing amounts of H₂S.

In addition to metal loss and pitting, sulfide stress cracking may occur in H₂S corrosion. The corrosion reaction generates hydrogen ions that

combine with electrons liberated in the corrosion process to form atomic hydrogen on the metal surface. Atomic hydrogen can penetrate the metal by diffusion where it can either interact with the metal lattice to form brittle cracking (sulfide stress cracking) or recombine at internal defects as molecular hydrogen. The molecular hydrogen generates high pressures, and the steel can suffer from blister cracking (hydrogen-induced cracking). This latter form of cracking is also referred to as stepwise cracking and under the influence of applied or residual tensile stresses, it is referred to as stress-oriented hydrogen-induced cracking (SOHIC).

Rod-on-tubing abrasion is common, and it aggravates corrosion reactions. Surface scale is removed, leaving bare metal. The adjacent areas covered with scale are cathodic to the bare metal and increase metal loss. Both the rod couplings and the tubing are damaged. Severe abrasion will lead to galling or removal of large portions of metal, which are literally torn away.

The flow velocities in pumping wells are generally not high enough to influence the corrosion rate, but localized areas of high velocity around rod protectors and restrictions due to scale buildup in the tubing could occur. High velocity or local turbulence can remove protective scale and inhibitor films, particularly if solids are present in the fluid.

Elimination of Sucker Rod Corrosion. Once the cause of the corrosion has been found, corrective action is required so that the problem does not recur. The first step is to determine if the pumping program is correct. If the rod string and pumping procedure are not dynamically balanced, excessive tensile and compressive stresses are applied that will hasten fatigue failure and sulfide stress cracking.

The range of load, that is, the difference between the load of the upstroke and the downstroke, should be kept to a minimum. Long strokes at low speed will give the lowest load. The load is due to the weight of the rods and the fluid column on the upstroke and the weight of the rods on the downstroke.

The upstroke causes stretching, and the downstroke releases this stress, causing flexing of the rod. This cyclic stress induces fatigue failure; therefore, minimizing stress will reduce breaks caused by corrosion-induced cracking.

Proper rod string makeup will also reduce failures. Recommended torque loading should be followed when making up the string to be sure that the coupling is not in excessive stress or is not subject to play or movement resulting from too little torque during makeup. Hitting the rods or couplings with hammers and the use of pipe wrenches on the string should be avoided to eliminate local cold working and damage that act as crack-initiation sites.

Fluid pounding should be avoided. Fluid pounding is caused by the pump not filling completely on the upstroke and the plunger hitting the fluid on the downstroke. The sudden stop of movement causes a shock wave to propagate up the rod string. Fluid pounding can be the most

damaging factor in rod failure. Rod guides can be installed to prevent rod-on-tubing wear.

Once mechanical deficiencies are eliminated, an inhibition program should be initiated. Corrosion inhibitors can prevent or greatly reduce failures caused by pitting or fatigue and will ensure that the changes made in rod loading and handling will be effective. Other methods of effective corrosion control include:

- Sucker rods are sometimes stored outdoors or in areas where internal storage is conducive to corrosion, such as coastal and industrial areas and in oil fields that produce H₂S. Oxygen corrosion or rust is aggravated by the deposition of salt from marine environments, such as spray on offshore platforms and coastal areas. In warehouses and under sheds, the presence of sulfur dioxide, oxides of nitrogen, and H₂S will initiate corrosive attack and increase rusting.
- The rod body and threads should be regularly inspected for corrosion damage. After inspection, the rods should be cleaned, and protective coatings should be applied.
- Suitable coatings that will provide protection for a minimum of 2 years should be applied by the manufacturer over rods and couplings. An oil-soluble coating is preferred, and it should be maintained by reapplication during storage. Used sucker rods should be cleaned and coated before storage.
- Sucker rods should be protected when pulled during workover operations. A batch of oil and inhibitor solution can be pumped into the tubing before pulling, or the rods can be coated after pulling.
- Couplings should be dipped in or brushed with an oil-inhibitor mixture before makeup. Care should be taken so that the amount of inhibitor added is not excessive. Thus, proper makeup can be performed.
- It is recommended that inhibitor be added to the tubing when the rods are run in the hole for initial filming. When the well is placed in production, one tubing volume of fluid should be circulated.

Once the well is in production, an inhibition and monitoring program should be initiated (Ref 93). An inhibitor is selected by testing for efficiency, usually with laboratory tests. These tests may include a wheel test, in which the inhibitor is added to bottles or high-pressure cells, rotated in a heated oven, and compared to an untreated control for percent protection and lack of pitting. Other tests include stirred kettle test and flow tests. All of these tests are designed to duplicate field conditions to a certain degree or to determine performance of inhibitors on different corrodents under specified conditions.

There are several methods by which the well can be treated. These include batch, continuous, and squeeze treatment, which are covered in the discussion "Inhibitors" in this section. See also "Inhibitors" in the section "Corrosion Control Methods" in this article and the discussion in the article "Corrosion Inhibitors for Oil and Gas

Production" in Volume 13A of the *ASM Handbook*. Other methods include tubing displacement after unseating the pump and the use of weighted inhibitors, sticks, or encapsulated inhibitors.

Downhole hydraulic pumps operate by pumping clean crude oil with a surface engine-driven pump down a string of tubing to operate a downhole hydraulic pump. The downhole pump lifts one barrel of fluid for each barrel of power fluid. The power oil is comingled with the produced fluid and separated on the surface. Problems can arise if the power oil carries water and solids or if CO₂, H₂S, or organic acids are present. The use of corrosion-resistant alloys or inhibitors can alleviate corrosion. Inhibitors are continuously added to the power fluid at the surface pump suction. Scale inhibitors and demulsifiers can also be added to the power fluid to prevent scale deposition and carryover of water into the power fluid.

In gas-lift wells, pressurized gas is injected into the annulus and through a gas-lift valve into the tubing. Fluid (oil/water) is displaced upward by the movement of the gas and out of the well. The process is repeated in batches or slugs in an intermittent system, or as a steady stream in a continuous-flow system. The velocities and local turbulence encountered with various flow regimes (slug, plug, etc.) may disturb normally protective surface films and thereby increase corrosion initiated by H₂S and CO₂. Corrosion-resistant alloys can be used in gas-lift valves, and steel tubing is usually protected by inhibitors. Alternative arrangements for controlling corrosion in the production tubing include the use of corrosion-resistant alloys.

Inhibitors are usually added into the lift gas at the surface and are carried with the gas stream into the tubing. Protection is provided above the lowest gas-lift valve. If corrosion occurs below the valve, inhibitor batch or squeeze treatments may be required for corrosion protection. The inhibitor selected for this application is usually oil soluble and water dispersible, and it can be diluted with liquid hydrocarbon to assist in carrying it downhole.

Flowing Wells

Corrosion problems in flowing wells are somewhat different from those encountered in artificial lift wells. Velocity becomes an important factor, and higher pressure leads to higher partial pressures of acid gases (i.e., CO₂ and H₂S). Treatment methods are more limited because of completion requirements.

Gas condensate wells may produce gas, hydrocarbons, formation water, acid gases, and organic acids. If the producing conditions allow liquid water to be produced or to condense on the tubing, corrosion is likely.

In wells producing formation water, corrosion may occur anywhere in the tubing string, wellhead, and flow line. Temperatures in the wellbore will affect the corrosion rate, and flow velocities also affect metal loss. The increased

salinity of the water and acid gas partial pressures generally increase the corrosion rates.

Wells that produce no formation water will corrode where the dew or condensation point of water held in the hydrocarbon gas is reached and free water condenses on the tubing. The water will immediately dissolve CO₂ or H₂S and become corrosive at that point in the well. This point can be located downhole in the tubing, or at the surface in the flow line leading from the well.

Carbon dioxide corrosion is particularly damaging in condensed water as it contains no buffering salts. Dissolved CO₂ can lower the pH of water to less than 4.5 at CO₂ partial pressures of 69 kPa (10 psi) and temperatures of 75 °C (170 °F). Carbon dioxide corrosion can cause severe localized mesa attack or pitting when conditions of temperature and salinity form iron carbonate scale in a discontinuous or spotty layer. Organic acids reduce pH and thereby increase CO₂ corrosion rates by dissolving normally protective iron carbonate scale and by lowering bicarbonate content so that further iron carbonate scaling is reduced.

Hydrogen sulfide can also be dissolved in produced water. Like CO₂ it acts as an acid gas. Metal loss and pitting, along with hydrogen-induced cracking and sulfide stress cracking, may occur.

Oxygen is not normally present in the production stream (unless brought in through processing—pumping or addition of chemicals), and it is generally not a problem. However, if it is introduced into the system, it will increase corrosion and pitting of steels and stainless alloys.

Materials Selection. Most gas wells are completed with low-alloy steels for economic reasons. These materials will perform satisfactorily in most wells, and the application of coatings and the use of corrosion inhibitors permit their use in severe environments of high temperature, pressure, and CO₂ content. However, there has been an increasing trend toward use of corrosion-resistant alloys for downhole tubing and equipment particularly in remote or offshore developments. If properly selected, these materials eliminate the need for use of chemical inhibitors and the associated equipment and logistics for inhibitor delivery, storage, and injection. This approach is discussed later in this section.

Many Tuscaloosa Trend wells in Louisiana, completed with carbon steel tubing, are producing with no corrosion failures when coated and inhibited. Producing conditions range to 205 °C (400 °F) bottom hole temperature, 124 to 138 MPa (18 to 20 ksi) pressure, and CO₂ content of 5% or more. Hydrogen sulfide is also found in some wells at concentrations of 20 to 50 ppm. However, the inhibitors used in extreme cases such as this are based on demonstrated efficacy through an intensive inhibitor screening evaluation. In other cases, 13% Cr tubulars and production equipment are being used without inhibitors.

Alloy Tubulars. When conditions and economics warrant, corrosion-resistant alloys can be

used. Steel with 9% Cr and 1% Mo has low corrosion rates up to 100 °C (212 °F). Higher corrosion rates and pitting become a problem at higher temperatures. The partial pressure of CO₂ is not a factor at temperatures below 240 °C (465 °F). Steel with 13% Cr is effective up to 150 °C (300 °F) or higher in the case of high-CO₂ gas wells producing primarily condensed water with low to moderate chloride levels (1500 to 10,000 ppm). More recently, new proprietary grades of modified 13 to 15% Cr martensitic stainless steel tubulars with alloying additions of nickel and molybdenum (see Table 3) have been applied at temperatures up to 230 °C (450 °F) and in conditions with higher levels of chloride and H₂S. Oxygen will cause severe pitting of 13% Cr steel; therefore, chemical injection systems must be kept oxygen free by an inert gas blanket on storage tanks. For example, the use of partially aerated seawater as a well control fluid has also resulted in severe pitting of 13% Cr tubulars.

If H₂S is present, 9% Cr steels can be used at hardnesses below 22 HRC to minimize sulfide stress cracking. However, 13 to 15% Cr steels are more resistant to corrosion as well as sulfide and chloride cracking, and they can be used under more severe conditions with higher H₂S partial pressures and at higher strength levels, particularly if modified alloys are used that contain nickel and molybdenum that are added to enhance corrosion resistance. For still higher levels of H₂S in combination with concentrated formation brine, higher alloy stainless steels and nickel-base alloys are also available (e.g., duplex stainless steels 2205 and 2507; austenitic stainless steels AL6XN, 254 SMO, and 654 SMO; nickel-base alloys 825, 625, and C276; precipitation-hardened nickel-base alloys 718 and 725; and titanium alloys).

There are still some concerns for corrosion, pitting, and stress cracking in martensitic and duplex stainless steel tubulars from clear brine packer fluids that may contain dissolved oxygen, CO₂, and/or H₂S. Careful selection of the packer fluid composition and additives to match the alloy corrosion resistance is recommended.

Coatings. Low-alloy steels can be coated for corrosion resistance. Coatings include baked-on phenolics, epoxies, and polyurethanes with fillers to give the required thickness, coating integrity, and corrosion resistance. Proper application is required for an intact coating that conforms to requirements. Tubing surface preparation, application methods, coating thickness, and holiday detection are part of the inspection and quality-assurance process.

Joints and connections should be designed so that the continuity of the coating is unbroken. The first few threads inside the coupling and the pin nose must be coated. A compression ring can be installed to ensure joint integrity.

Special care must be taken when the wireline operations are carried out in the coated tubing. Coatings are easily damaged or scratched, and once the coating is broken, corrosion and disbonding of the remaining coating can take place.

Wireline guides and running speeds of less than 0.5 m/s (100 ft/min) will minimize damage. A corrosion inhibitor should be used during or directly after wireline operations. The wireline tools should not have sharp edges and should be plastic coated. Wireline centralizers should also be used.

Coatings are also subject to disbondment if pressures are released suddenly (i.e., explosive decompression). Gases can penetrate the coating, and when a sudden pressure drop occurs, the gases will expand and lift the coating from its substrate.

Inhibitors. Corrosion inhibitors are an effective means of corrosion control, and they are required in highly corrosive environments in which carbon steel is used. They are needed even if the tubing is coated, because a holiday-free coating does not exist. Combination coating-inhibitor procedures are particularly effective provided the application is below the temperature limits for the coating and inhibitor.

The most commonly used inhibitors function by forming a film on metal surfaces that stops the flow of corrosion current. Nearly all inhibitors are fatty amines or quaternary ammonium compounds. The nitrogen in the molecule possesses a strong cationic charge and is chemically absorbed onto anodic sites on the metal surface. Cross-bonding of the inhibitor film and the attraction of a layer of oil aid in isolating the surface from the corrosive environment, thus promoting effective corrosion protection.

Inhibitors are selected for several characteristics. The major consideration is their performance in terms of providing low corrosion and pitting rate. Next, performance must be considered for inhibitor-film persistence, compatibility with production fluids and formations, and emulsion tendencies.

Once an inhibitor is selected, a treating method is used that fulfills the system requirements. Several methods are commonly used to treat flowing wells: batch treating, continuous injection, and squeezing are discussed here.

Batch treating involves the intermittent addition of relatively large quantities of inhibitor solution to the annulus or down the tubing of a gas condensate well. A batch treatment in a flowing well consists of dosing a solution of inhibitor in hydrocarbon condensate or diesel fuel. It can be applied down the tubing, shutting the well down to allow the inhibitor solution to fall to the bottom, and repeating at a set interval. The disadvantage of this treatment is that the inhibitor may not go to the bottom. The tubing may contain up to 50% of its volume of water and oil, and the bottom of the well below the static shut-in fluid level may not be treated using this method.

A method of treatment that ensures that the batch will reach the bottom of the well is tubing displacement. A batch of inhibitor in oil, usually one-third of the tubing volume, is pumped into the well, and enough condensate or oil is pumped in to displace the batch to the bottom. The well is shut in for a few hours and brought back on

production. This procedure ensures that the tubing is treated with inhibitor all the way to the bottom. Inhibitor treatments involving tubing displacement may last from a few days to a month or so, depending on the severity of the corrosion problem, the produced fluids, the flow velocity, and the ability of the inhibitor to form a persistent film.

Nitrogen or another gas can be used to displace the inhibitor solution instead of liquid. This is of value if the well has a low bottom hole pressure. In these cases, filling the tubing with fluid may permanently stop production or "kill" the well. It is also of value where volumes of oil cannot be easily handled. A variation of the nitrogen batch is to atomize the inhibitor solution into the nitrogen as it is pumped into the well. For batch treatments, the inhibitor selected must have good film persistency as it is not replenished until the next batch treatment is made.

Continuous injection consists of a constant addition of small concentrations of inhibitor into a producing well. The chemical can be added into a chemical or capillary string or down the annulus of a packerless completion. Chemical injection valves in a side-pocket mandrel can be installed so that the solution can be pumped continuously into the annulus of a well with a packer.

The Tuscaloosa Trend wells were originally completed with a Y-block and kill string. This string was used for chemical injection. Wells were then completed with a packer and a chemical string and later with a packerless completion where the inhibitor was added down the annulus.

In treating deep, hot wells, the inhibitor is added as a dilution in hydrocarbon condensate (e.g., carrier oil). This is necessary because the gas is undersaturated with hydrocarbon. At high pressures, gas acts as a liquid and may strip the solvent from the inhibitor. The amount of condensate is calculated to saturate the gas. Another consideration in continuous inhibitor injection in deep, hot, high-pressure wells is the phase behavior of the carried oil. In some cases, the hydrocarbon condensate is replaced with a heavier, less volatile oil that will remain liquid even under the extreme bottom hole conditions in these wells. In some cases, wells have been treated with water-soluble inhibitors in a water-solution or as a dispersion of inhibitor in water instead of hydrocarbon condensate.

Capillary strings are small-diameter, armored tubing that is placed in the annular space between the tubing OD and casing ID. This tubing is strapped to the outside of the tubing as it is run into the well. A surface tank, pump, and filter are installed. The filter is necessary to prevent particles from plugging the small-diameter tubing. Inhibitors must be selected for this application that do not solidify or polymerize, because this would also plug the capillary, making it unusable.

A method of treating a well with a packer consists of using a perforating gun to shoot holes in the tubing. The inhibitor is pumped down the

annulus and through the holes. This method is said to be more economical than recompleting the well with alternative equipment necessary for continuous inhibitor injection.

Continuous treating of deep, hot wells requires an inhibitor that will not break down or form a gunk or char. This is particularly important in wells treated with a capillary string or down the annulus where the inhibitor solution must remain for an extended period of time at high temperature. A surface filtering system is also required for capillary string treating to eliminate particulate impurities in the injected fluids.

The deep, hot wells in the Tuscaloosa Trend require an inhibitor that will withstand temperatures to 230 °C (450 °F) without breaking down. Although the chemical strings in the wells that have not been converted to packerless completions are large in diameter (25 to 50 mm, or 1 to 2 in.), plugging problems may occur. Most of this is due to salt plugs, and the condensate has a natural fouling tendency. Therefore, any tendency to form an insoluble residue by the inhibitor adds to the problem. A high-pressure, high-temperature stability test is run in produced fluids to ensure the stability of the inhibitor against formation of precipitates. The dosage of inhibitor used for deep wells will normally range from 10 to 100 ppm under most conditions. Extremely corrosive wells may require more.

Squeeze treatment involves placing an inhibitor solution far enough into the producing formation from the wellbore so that a continuous feedback of inhibitor is obtained during subsequent production of the well. The volume of the squeeze treatment is sized so that a predetermined life is obtained based on the production rate of well fluids. Field crude, hydrocarbon condensate, or diesel oil are commonly used as diluents for squeeze treatments.

The inhibitor must have the proper solubility in the diluent, and it must not form a gunk or severe emulsion with produced water in the formation. Either condition could cause temporary or permanent loss of reservoir permeability and subsequent loss of well production. A core test is sometimes conducted to help select an inhibitor for a tight (fairly low permeability) formation. This involves testing the inhibitor formulation in a core sample of formation rock and then evaluating the core sample for permeability of hydrocarbons. Film persistence is not as important as continuous protection, because inhibitor will be present in the production stream at all times.

In some reservoirs, hydrocarbon condensate is above critical temperature and therefore exists as a gas. This condition is known as a retrograde reservoir, because when the pressure is lowered, condensate comes out of solution with the gas, rather than the normal condition in which lowering the pressure vaporizes the condensate. A dry reservoir that contains no liquid condensate should not be squeezed. Permanent loss of relative permeability will occur, and gas production

rates and hydrocarbon recovery will be decreased.

One common objection to squeezing is that inhibitors are cationic and will oil-wet the formation. The wetting characteristics of a surface-active material are based more on its hydrophilic-lipophile balance (HLB), which is a measure of the tendency of the inhibitor to water-wet or oil-wet a surface, than on reservoir properties. The HLB is determined by the size and type of oil- or water-soluble parts of the molecule. Nonionic surfactants are used to oil-wet metals in lube oils and are used to water-wet materials in cleaners. Sulfonates are excellent water wetters, while other sulfonates are used as oil wetters. Cationics follow the same rules. In fact, polyamines and quaternary ammonium compounds are used in workover fluids to water-wet silicates.

It is most likely that some oil wetting of the formation occurs (the inhibitor goes into the oil in the reservoir). This is what causes a squeeze to work. Nevertheless, any change in the wettability of the formation is reversible. The formation immediately begins to return to its original state once the wetting agent is removed or begins to dissipate. Natural or simulated core tests can be conducted to ensure that no formation damage will occur from the inhibitor.

Loss of production can also result from a squeeze treatment due to the formation of a stable emulsion in the area immediately adjacent to the wellbore. This emulsion is nearly always a water-in-oil emulsion, which is very viscous. The high-viscosity emulsion will not flow through the pore throats. Emulsion blocking can be prevented by proper inhibitor selection and by adding demulsifiers to the squeeze formulation. A typical squeeze can be performed in the following manner. First the amount of inhibitor required for the projected life of the squeeze should be calculated using:

$$V = \frac{42 \cdot P \cdot D \cdot 3 \cdot \text{ppm}}{1,000,000} \quad (\text{Eq } 7)$$

where V is the volume of inhibitor (gallons), P is the total daily production in barrels (including both oil and water), D is the expected squeeze life, and ppm is the amount of inhibitor feedback desired (this is multiplied by 3, because it is assumed that only one-third of the inhibitor will remain in place that will desorb and feed back). The remaining five-step procedure is to:

1. Dilute the inhibitor with crude, hydrocarbon condensate, or diesel oil to 10%
2. Pump a spearhead of 5 to 10 barrels of oil with 19 L (5 gal) of demulsifier
3. Pump the main body of the squeeze treatment into the formation
4. Overflush with one tubing volume plus one day's production volume of oil (19 to 38 L, or 5 to 10 gal, of demulsifier can be added to the overflush)
5. Shut in the well for 12 to 24 h

This procedure can be modified to suit the requirements of a particular situation.

In many applications, the amount of overflush needed to place the inhibitor properly is too large, or filling the tubing may kill a low-pressure flowing well. The use of nitrogen instead of hydrocarbons overcomes these restrictions.

In a nitrogen squeeze, the inhibitor solution is displaced downhole and into the formation with an equivalent amount of nitrogen. This leaves the tubing empty and charges the formation so that it flows back readily.

This procedure can be modified so that the inhibitor solution is atomized into the nitrogen as it is injected. Both of these procedures have been used with excellent results. The wells could be returned to production in 4 h, and due to the charging effect, the increased production rates for a day or so compensated for the production loss during the squeeze.

Corrosion Monitoring

Once the well, line, or vessel is treated, it is necessary to evaluate the effectiveness of the treatment program and to determine when to retreat or change dosage levels. The methods used include iron counts, weight-loss coupons, test nipples and spools, and probes that use electrical resistance and electrochemical techniques. A last-resort method of waiting until the tubing failure is sometimes available but not popular with operators. However, the collection of tubing failure or perforation data is a valuable source of information.

Iron counts consist of taking a representative sample of produced water and testing for dissolved iron content. The sample must be representative for the system; therefore, the sampling location and procedure are important. The iron counts can be plotted for easier understanding (see Fig. 18). Data management programs are available that will present iron counts, or the data can be simply placed in a spreadsheet for display and plotting. Care must be taken so that the iron from the formation is not assumed to be metal loss from the tubing. Some of the deep, hot Tuscaloosa Trend wells produce water with more than 100 ppm of iron. A base count should be conducted on a downhole sample, if possible. Iron counts are of moderate effectiveness in sweet gas (CO_2) wells. In cases where H_2S is present, dissolved iron counts are not effective since the dissolved iron will react with H_2S in the environment to produce iron sulfide, an insoluble species.

Corrosion coupons are flat or cylindrical pieces of metal that can be installed in nearly any accessible location in the system. It must be remembered that coupons measure corrosion only where they are placed. Furthermore, they only show average corrosion rates over the period of their exposure to the produced environment. Coupons show corrosion after it has taken place, and a single coupon will not show whether the corrosion occurred uniformly with time or occurred over a short interval during the exposure period. Additionally, to properly conduct a

coupon monitoring program, significant labor is required to place, retrieve, evaluate, and interpret the corrosion coupons. This is totally an off-line process. Corrosion coupons do however offer the advantage that the morphology of the corrosion (e.g., general or localized attack, pitting, etc.) can be easily seen by visual examination.

Different types of coupon holders are used, depending on the system, the pressure, the location, or other factors. Most coupons are run on surface facilities or flow lines in a 25 or 50 mm (1 or 2 in.) threaded plug. Flat coupon holders hold two coupons, while cylindrical coupon holders may contain eight or more coupons. Some coupons holders allow coupons to be pulled at successive intervals to see if the corrosion rate is constant with time or not.

High-pressure systems require special coupon insertion devices. The insertion tool fits into a special attachment on the pipe or vessel that has a high-pressure chamber with a valve on each end. The inner valve is closed, the retrieval tool inserted, and the inner valve opened. The tool is then run in and left. The procedure is reversed to remove the coupon.

The industry guide for preparing, installing, and interpreting coupons is NACE standard RP0775 (Ref 94). The primary consideration is that all coupons be treated exactly alike. Detailed procedures for preparing corrosion coupons and methods of cleaning for determination of corrosion rates are given in ASTM G 1 (Ref 95). A method of preparation that does not alter the metallurgical structure of the coupon is required. Grinding and sanding of coupons should be controlled to avoid metallurgical changes and to provide a consistent and reproducible surface finish.

Coupons should be handled carefully and stored in chemically treated envelopes or paper until they are installed and should be solvent cleaned and rinsed before use. Rust spots caused by improper handling, fingerprints, and so on, may initiate local attack that is not representative of the system being evaluated. Prior to installation, the coupon weight, identification number, date installed, name of system, location of coupon, and orientation of the coupon and holder should be recorded. The coupons are left in the system for a predetermined number of days and then removed. The frequency of coupon removal is usually in overlapping periods of 30 to 120 days depending on the corrosivity of the system and tendency for periodic upsets.

When the coupons are removed, the identification number, date removed, observations of any erosion, pitting, crevice corrosion or mechanical damage, and appearance should be recorded. A photograph of the coupon may be valuable in some cases. The coupons should then be placed in a moisture-proof envelope impregnated with a vapor-phase inhibitor and taken immediately to the laboratory for cleaning and weighing. The coupons can be blotted (not wiped) dry prior to placing in the envelope. Once at the laboratory, the coupons are weighed before cleaning, cleaned, reweighed, and then

photographed. This type of analysis will give useful information in terms of both scale weight and mass loss and the morphology of corrosion. Sometimes the corrosion products are analyzed for elemental composition or the specific chemical compounds by x-ray analysis. A report is issued showing the corrosion rate, any pitting observations, and any other observations of interest. ASTM G 46 (Ref 96) gives useful procedures that can be used to characterize and define the nature of any localized attack on the corrosion coupons.

Electric resistance (ER) instruments function by reading the resistance to current flow of a thin loop of metal installed in the system. The loop of metal is part of an electrical Wheatstone bridge circuit. As the loop corrodes and loses cross-sectional area, electrical resistance increases, and the current flow decreases. This unbalances the bridge and reads out directly on a meter. It may also be recorded on a strip recorder, or with current instruments the data can be logged and then downloaded to a computer for display, trending, and further analysis in spreadsheet format. As the reading changes, the points are plotted on a time graph. The slope of the line is translated into a corrosion rate. The slope will change when a well is treated (decreased slope—lower corrosion rate) or when a corrosion event occurs (increased slope) that changes corrosion rate.

The metal loop is fragile, and it can break if foreign objects, scale, or similar obstructions are present in the flow. The loop may become coated with paraffin, oil, or particulates and may not give a true reading. There are two important limitations of ER measurements. They cannot be used to assess pitting corrosion. Secondly, conventional ER measurements are not instantaneous measurements. Consequently, they are of only limited use in online monitoring. They basically act as instrumented coupons. Normally, the time period required to determine a change in the resistance trend line is longer than that required for process-control needs. Therefore, they provide average corrosion rate information. Recently, more sensitive ER devices have been developed that produce more rapid corrosion rate readings. However, these are used to assess general corrosion tendencies without being able to assess localized corrosion.

Electrochemical instruments monitor the potential and current signals resulting from the corrosion of probe elements that are made from the same or similar materials as used in the system being monitored. The simplest of these devices is called a galvanic probe and uses a two-element, dissimilar electrode arrangement. This device measures the galvanic current produced between the dissimilar metals whenever a corrosive environment is present. In this case, the signal is qualitative in nature (high current when corrosive conditions exist and little or no current when conditions are not corrosive) and does not provide actual corrosion rates.

Linear Polarization Resistance. For semi-quantitative applications a two- or three-

electrode arrangement is used to make linear polarization resistance (LPR) measurements. The difference between the two- and three-electrode LPR instruments is that with the three-electrode version, it is possible to measure and compensate for the IR drop in the environment that can be an additional source of corrosion rate error. This version is particularly useful in low-conductivity solutions. For additional information on the background and application of the polarization-resistance method discussed below, the reader should refer to Volume 13A of the *ASM Handbook* (see, for example, the article "Electrochemical Methods of Corrosion Testing").

The LPR technique varies the potential slightly of one electrode (± 25 mV) from its normal corrosion potential and monitors the resulting current produced in the two- or three-electrode circuit. The slope of these data is referred to as polarization resistance (R_p), which is normally considered to be inversely proportional to the corrosion rate. Using Faraday's law, the Stern-Geary equation, and the physical information on the material and probe size, this current can be converted to a general corrosion rate for the material. Measurements can be taken at intervals of 20 to 30 min or as needed, which makes this technique attractive for process-control purposes.

One aspect of this technique that limits its quantitative use is that simple field LPR devices cannot measure the actual anodic and cathodic Tafel slopes used to calculate the value of the Stern-Geary parameter (B value). An accurate B value is needed to obtain an exact conversion from corrosion current to corrosion rate. In the laboratory, it is customary to measure these parameters for use in accurate corrosion rate determinations. However, in field measurements, it is customary to provide a fixed, default B value in these LPR instruments of between 0.025 and 0.030 V depending on the manufacture. This provides reasonable conversion for many applications except where the corrosion processes dictate a much different B value. Additional techniques have been developed that make it possible to measure the Tafel slopes and B values without a laboratory-style potentiostat.

An automated variation of the LPR technique and its analysis available in certain field instruments is known as harmonic distortion analysis (HDA). In this application, a continuous low-frequency (15 mHz) symmetrical sine-wave polarization signal is employed to measure both the overall polarization resistance, R_p , and the solution resistance, R_s . The leading edge of the wave acts as a high-frequency perturbation and effectively short circuits the double-layer capacitance, thereby allowing R_s to be measured. The dc component of the current response is used to measure R_p , and by subtraction, the charge transfer resistance can be obtained. Two distinct benefits of the field use of the HDA technique is the determination of the anodic and cathodic Tafel slopes for use in assessing and controlling

inhibition, and the B value (Stern-Geary factor) for use in correcting LPR corrosion rates (Ref 97).

In most cases in oil and gas operations, corrosion measurements are made in the liquid (brine or mixed brine/oil environment with dissolved gas) where the electrodes protrude into the liquid phase. Alternatively, corrosion measurements need to be made in a wet vapor phase where the electrodes are covered by a thin film of aqueous fluid and/or oil and dissolved gases that condense from the vapor phase. Special flush-mounted probes are required with closely placed (and interlaced) electrodes. Custom probe designs can extend corrosion monitoring into mixed oil/water environments and in condensing-vapor-phase conditions as well as optimize the electrode configuration for monitoring in multiphase environments. Alternative probe configurations also include flange or gasket probes that can be placed in the gap between existing flange connections. These probes eliminate the previous requirement of locating and installing an access fitting in the system. They also provide an electrode configuration that closely models the ID surface of the pipe or piping system being monitored. B value measurements are very important in making accurate corrosion rate measurements in these types of multiphase field environments and where the influence of H_2S or other strongly depolarizing species need to be factored into the corrosion measurement.

As mentioned previously, B values are not instrument constants (as commonly believed) but are actually defined by the corrosive conditions that exist on the metal surface and commonly include: (a) the oxidation of iron to iron ions, (b) corresponding reduction reactions, (c) ionic current flow in the media, and (d) electronic current flow in the metal.

Therefore, knowledge of the actual B value is quite useful in providing insight into corrosion processes. High values of B would tend to indicate the corrosion processes are tending to be rate limited due to diffusion processes (this *does not* necessarily mean slower). Alternatively, low values of B would suggest that the system being studied is nonpolarizable, likely due to the presence of certain chemical species that tend to depolarize the electrode.

From an electronic viewpoint, an activation (Tafel) slope of 60 mV per decade of current would relate to a single electron transfer process. Table 9 helps to understand the various values of B and their origin.

A common case is in the second horizontal row of Table 9, which has led to the widespread adoption of 25 to 30 mV B values in most field-monitoring instruments. An example of a case where such B values are appropriate is for carbon steel in aerated seawater or brine.

Higher B values typically occur because of diffusion-limiting effects on both the anodic and cathodic processes. Very high B values have typically been observed with very high corrosion rates or in some cases where thin films

(vapor-phase exposures) or oil/water mixtures are present.

Low B values have been observed with the presence of reactive sulfide species in the environment leading to the formation of sulfide corrosion films on the metal surface (which are also the cause of changes in the measured double-layer capacitance and apparent “shorting” between electrodes in some cases). The sulfide films resist the applied polarization (are nonpolarizable), which is most likely the result of a strong redox process within the sulfide film.

In corrosion measurements, even though corrosion rates and polarization resistance (R_p) are inversely proportional, low polarization resistance values do not necessarily mean high corrosion rates and high polarization resistance values do not necessarily mean low corrosion rates. It is only through field corrosion measurements that incorporate measured B values that accurate corrosion rates can be obtained. Not to incorporate measured B values can easily result in corrosion rate errors of 25 to 50%, and in some cases, the errors can be over an order of magnitude (Ref 98).

Electrochemical Noise (EN). A relatively new technique applied to field corrosion measurements is EN, which was developed in the 1970s for laboratory and research applications. Electrochemical noise is the measurement of spontaneous fluctuations in the current and potential generated by corrosion occurring at the metal-electrolyte interface of a three-electrode system (Ref 99). Ideally, the sensors for EN measurements comprise two identical working electrodes plus a reference electrode. Whereas in the laboratory, the reference electrode is usually a conventional solute electrode (such as Ag/AgCl or standard calomel), for practical field monitoring applications, a metal pseudo-reference electrode of the same material as the working electrodes is typically used. This is similar to the standard three-electrode configuration used for field LPR measurements, which leads to the use of three nominally identical electrodes made from the material of interest in the evaluation.

Modern microchip computing capabilities and telecommunications have allowed this technique to be remotely located near the point of monitoring. Automated statistical analysis of the current and potential time records are used to

derive a pitting factor (defined simply as the standard deviation of the corrosion current derived from EN divided by the average corrosion current during the measurement period from LPR) to infer tendencies for general or localized corrosion. Using this methodology, conditions for pitting are identified when the pitting factor is above 0.1 (e.g., the standard deviation of the EN current noise is above 10% of the corrosion current). Conditions for general corrosion are commonly associated with low value of pitting factor (less than 0.01). The intermediate decade (pitting factor = 0.01 to 0.1) should be considered a transition or cautionary range. It does not indicate active pitting, but signifies unstable conditions on the corroding metal that can be easily perturbed to higher values by changes in process variables (e.g., flow rate, turbulence, chloride, oxygen, etc.).

It is actually more important to know if pitting is an active process rather than to know its pitting rate, which can be highly variable from pit to pit. Pitting is an inherently unstable process, and efforts should be made to control processes, operations, and the production environment to minimize pitting tendencies. Since pitting often results from upset conditions, real-time monitoring is often needed to successfully control pitting. Electrochemical noise can also be used to derive corrosion rates; however, these values are not normally used for real-time, process-control applications except in rare situations.

The principal advantage of these newer electrochemical instruments with EN capabilities is that a corrosion rate can be determined immediately (normally within 7 min), and pitting tendencies quickly assessed without waiting a month or more to retrieve coupons. Figure 23

Table 9 Origin of various B values (corrosion parameter) for use with linear polarization resistance corrosion measurements

β_a	β_c	B	Comments
60 mV	60 mV	13 mV	Both processes activation controlled; commonly observed with sulfide species
60 mV	∞	26 mV	Anodic process activation, cathodic diffusion, controlled; commonly observed with aerated brine
120 mV	∞	52 mV	Anodic process activation, cathodic diffusion, controlled (anodic slope different); commonly observed with oil/water mixtures
∞	∞	∞	Severe anodic and cathodic diffusion limiting; commonly observed in condensing vapor phase conditions

Note: $B = \beta_a \beta_c / 2.3 (\beta_a + \beta_c)$, where β_a and β_c are the anodic and cathodic Tafel slopes, respectively.

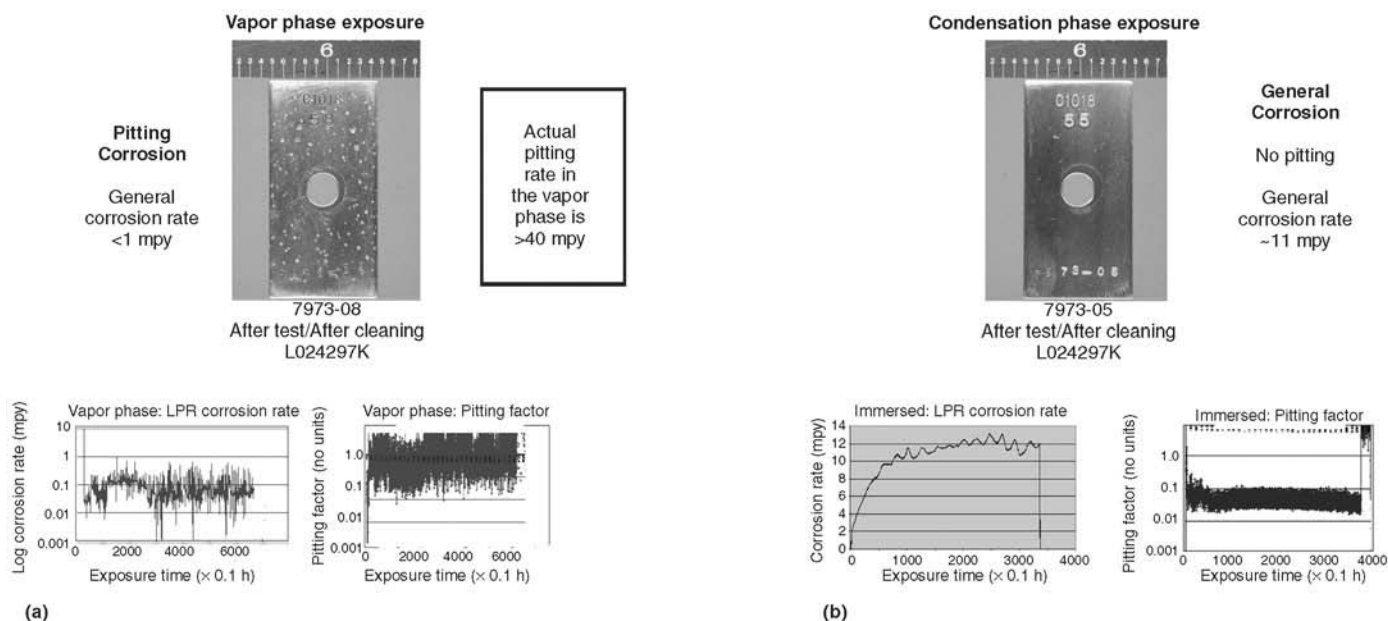

Fig. 23 Differences in corrosion rate and modality—(a) pitting and (b) general corrosion—as determined by automated, real-time electrochemical corrosion monitoring system using linear polarization resistance, electrochemical noise, and harmonic distortion analysis. Note comparison of electrochemical data from a partially dehydrated CO_2 gas pipeline liquid phase water/glycol and condensing vapor phase in system. Corrosion rates are given in mils per year (mpy). Source: Ref 100

shows a comparison of coupon examination and mass loss determination versus real-time, online monitoring data using an electrochemical device incorporating LPR, HDA, and EN techniques (Ref 100). It can be seen that the corrosion rate and pitting factor obtained by electrochemical monitoring provide accurate assessment of pitting and general corrosion within a time frame of hours. The coupon data required exposure for a period of about 1 month. While corrosion coupons and electrochemical techniques provide similar data, the online, real-time electrochemical data would allow the operator to take corrective measures (e.g., process change, inhibition, etc.) before substantial damage has occurred.

Probe locations are very important, because conventional, electrochemical "finger" probes must be immersed in water to give an accurate reading. As discussed previously, alternative flush-mounted, flange or interleaved designs can be used that optimize the probe electrode configuration for measuring corrosion in mixed-phase water, oil, and gaseous environments. Probes can become coated with oil, paraffin, or corrosion products and can show an erroneous corrosion rate. They should be located in the bottom of a line (5 or 7 o'clock positions) or in a bypass loop so that they are water wetted. The use of field B value (Stern-Geary factor) measurements should be used to obtain more appropriate corrosion rates from electrochemical probes. The B value is not an "instrument" constant. As mentioned previously, the chemical composition of the environment and the mixed-phase conditions (i.e., oil, water, and/or gas) can influence the B value, which can be used to correct conventional LPR corrosion rates.

Other Corrosion Assessment Techniques. A test loop can be installed in a system for better monitoring and control. A test loop is simply a bypass with valves for controlling flow, and it may contain weight-loss coupons as well as probes. The system can be monitored, and different inhibitors can be evaluated at the same time. A bypass test loop can also allow for removal of coupons and probes periodically for inspection and analysis.

A caliper survey of the downhole tubing can be conducted to determine if pitting and general metal loss have been halted. The caliper log can be easily compared with a long run before the treatment is begun.

Other monitoring methods include hydrogen probes and in-line electromagnetic logging devices (e.g., smart pigs). Chemical analysis of produced water for alloying metals, such as manganese and chromium, can also be conducted.

It is important to collect and chart failure rates. Some failures may occur over a period of time and may erroneously indicate that the treatment is not effective. However, through proper charting and comparing with previous failure rates, the effectiveness of proper treating will be shown.

Corrosion in Secondary Recovery Operations

Secondary recovery, or waterflooding, generally increases the corrosion problems in existing producing wells. It also creates a new set of problems because of the facilities required to reinject the produced water. This section discusses the corrosion problems that are specific to the various types of environments or equipment used in secondary recovery, that is, producing wells, producing flow lines, separation facilities, tanks, injection pumps, injection lines, and injection wells. Although not specifically addressed, disposal wells (wells that are used for produced water disposal rather than reinjection into producing formations) are considered to be the same as injection wells. Corrosion mitigation methods and guidelines are then discussed for each type of environment.

Types of Corrosion Problems

Producing Wells. The corrosion mechanisms in secondary recovery are similar to those in primary production. The primary causes of corrosion are dissolved acid gases (H_2S and CO_2) in the produced fluids. Naturally occurring organic acids are often present and can aggravate H_2S and CO_2 problems. Corrosion will generally increase in secondary recovery because of the large increase in water production caused by waterflooding. The fraction of water produced versus total liquids (aqueous and hydrocarbon), also known as water-cut, may increase to 90% or more. This increases the potential for corrosion, because more of the metal surfaces may be water-wet rather than oil-wet. The increased volume of water can increase pumping equipment stresses. Increased stress levels can cause more corrosion fatigue related failures.

Corrosion mechanisms may change during waterflooding. For example, a normally sweet field (that is, the produced fluids contain no H_2S) may begin to produce H_2S because of the growth of sulfate-reducing bacteria in the formation. This can cause unexpected corrosion related to the H_2S , pitting under sulfate-reducing bacteria deposits, or failures from sulfide stress cracking in high-strength materials.

Mineral-scale problems, such as the deposition of $CaCO_3$, $CaSO_4$, or $BaSO_4$, may increase during waterflooding. This is usually the result of changes in the formation water brought about by injecting waters from sources other than the original reservoir. Although not strictly a corrosion problem, scale deposition can cause increased failures due to wear and underdeposit corrosion.

Producing Flow Lines. Corrosion mechanisms in producing flow lines are similar to the mechanisms downhole, but generally occur at a lower rate because temperatures and pressures are lower at the surface. Corrosion is often localized to the bottom of flow lines if flow rates are low enough to permit water stratification,

which allows the bottom of the line to be continuously water-wet. Underdeposit corrosion and sulfate-reducing bacteria related pitting are often severe under sludge or scale deposits that accumulate in the low flow rate lines.

Oil/Water Separation Facilities. Corrosion in these facilities is normally related to attack by corrodents in produced fluids and deposit-related problems. Separation facilities are unique in that they often use heat to aid in oil/water separation. Heat-transfer surfaces are usually subject to mineral-scale deposition because of solubility changes caused by temperature increases. Scale deposition can result in severe underdeposit corrosion because metal surface temperatures increase due to the reduced heat transfer. Creep rupture failure can occur in direct fired heaters if deposition is severe enough to cause very high metal temperatures. Some separation equipment is open to the atmosphere, thus allowing oxygen contamination of the produced fluids and causing increased corrosion in equipment handling the water phase.

Tanks/Water Storage. Tanks are subject to corrosion by acid gases (CO_2 , H_2S) carried over with the produced water. Underdeposit corrosion can be severe under accumulated sludge and debris in tank bottoms. These deposits are also prime areas for the growth of sulfate-reducing bacteria. Tank roofs often fail because of condensation. As water condenses on the roof, it will absorb acid gases from the tank fluids. This can cause severe pitting. Oxygen contamination often occurs in tanks. Obviously, open tanks are subject to contamination. Contamination can occur in normally closed tanks if hatches and vent systems are poorly maintained. Although oxygen can be somewhat corrosive by itself, its primary role in waterflood system corrosion is to significantly increase the rate of attack of other corrodents already in the system.

Injection pumps can fail by normal corrosion mechanisms as well as by cavitation and erosion. Pump intake piping design must take into account the presence of dissolved H_2S and CO_2 in the water. These gases can affect net positive suction head calculations. If sufficient net positive suction head is not provided, cavitation can occur. Erosion and erosion-corrosion can occur because of solids in the water. Solids normally consist of corrosion products, formation fines, and mineral-scale particulates. Alloy materials such as type 304 and 316 stainless steels are often used for pump internal parts. These alloys can fail by chloride SCC in produced brines if temperatures are above 52 to 65 °C (125 to 150 °F). Pumps are subject to cyclic stresses. Corrosion fatigue failure can occur at sharp changes in cross section, grooves, and at pitted areas, all of which cause stress concentrations.

Injection Flow Lines and Wells. Corrosion mechanisms are generally the same for producing well flow lines and tubulars, that is H_2S , CO_2 , and organic acids. Underdeposit problems in the bottoms of lines and under mineral-scales can also occur, as can problems with

sulfate-reducing bacteria. Oxygen contamination will greatly accelerate all but the sulfate-reducing bacteria mechanism. Sulfate-reducing bacteria corrosion can still occur even in aerated systems because localized areas under scales, sludges, or aerobic bacterial slimes can become anaerobic and thus support the growth of sulfate-reducing bacteria.

Injection wells and flow lines may require periodic acidizing to reduce pressure drops and to restore the injectivity lost because of the buildup of corrosion products and mineral scales. Severe corrosion can occur if acidizing fluids are not properly inhibited and flushed from the system.

Corrosion Mitigation Methods

Producing Wells. Corrosion control methods for secondary recovery are typically the same as those used for primary recovery; however, higher levels of water in both gas and oil production, and souring (e.g., an increase in H_2S concentration) should be anticipated as the wells age. The particular method implemented will depend on the type of production method and rate used (that is, beam lift, electric submersible pump, or gas lift), the nature of the produced fluids, well design, and the economics of the individual situation.

Corrosion inhibitors are widely used to protect tubulars and other downhole equipment in all types of producing wells. The most common methods of sending the inhibitor downhole where it can protect the well equipment are referred to as squeeze treatment, batch treatment, and continuous treatment (see the discussions "Inhibitors" and "Oil Production" in this article). References 92 and 93 contain detailed descriptions of the various methods as well as guidelines for selecting a particular method. Regardless of the method used, the inhibitor must be effective against the particular type of corrosion occurring, that is, H_2S , CO_2 , or both, or even cases where oxygen may be present due to contamination from surface operations. Laboratory tests should be performed if there are any questions regarding the effectiveness of the inhibitor for a given type(s) of corrosion.

The type of corrosion inhibitor used (oil-soluble, oil-insoluble, water-dispersible, water-soluble, and so on) will depend on the treatment method. Batch treatment is a widely used method of treatment for beam lift wells. Corrosion inhibitor solutions are periodically injected into the casing-tubing annulus and flushed to the bottom of the well with produced fluids, diesel oil, or water. A water-dispersible inhibitor is normally used because of the high percentage of water in the well stream. However, increased water dispersibility can cause problems with oil/water separation because of the tendency for dispersion chemicals in the inhibitor to cause emulsions to form. Tests should be performed with actual well fluids to determine the emulsion tendency of the particular inhibitor being considered for use.

Often, any one of several inhibitors may be able to provide the necessary corrosion protection; however, there will be vast differences in emulsion formation and economics specific for the application at hand.

Continuous injection of inhibitor may be necessary for wells with high fluid levels in the annulus above the pump. Water-soluble inhibitors are normally specified for this type of treatment. Studies have shown that continuous treatment may not always be as effective as periodic batch treatment under many conditions (Ref 92). Emulsion problems are sometimes worse with water-soluble inhibitors than with oil-soluble or water-dispersible inhibitors because of the increased use of surfactants in water-soluble inhibitors. In order to sort out these types of problems, it may be necessary to conduct laboratory or field studies on emulsion-forming tendencies and the effectiveness of emulsion-breaking chemical additives to achieve optimum production conditions.

The frequency of treatment and the quantity of inhibitor used will generally have to be increased during secondary production, as the amount of water and possibly corrosive species increase. In general, it is more effective to increase the frequency of inhibition (assuming a batch treatment procedure is used) rather than the quantity, although both may need to be adjusted in some cases. Treatment should be adjusted on the basis of corrosion monitoring results and well equipment life. Corrosion monitoring can be accomplished in a variety of ways. Corrosion coupons installed in flow lines near the wellhead are the most common. Downhole monitoring is more difficult. Prewedged, short (0.6 m, or 2 ft) sucker rods can be used as downhole corrosion coupons, as can short joints of production tubing. Information on the preparation, installation, and evaluation of corrosion coupon data is provided in NACE RP0775 (Ref 94).

Downhole equipment should be carefully examined for signs of corrosion whenever it is removed from the well. The occurrence of sucker rod failures is a common measure of downhole inhibition effectiveness in rod pumped wells (Ref 93). The number of failures that can be tolerated will depend on the economics of each producing situation. A general guideline is one corrosion-related failure per well per year. It should be remembered that corrosion fatigue failures of sucker rods are a function of corrosion and stress. Therefore, heavily loaded rods will tolerate less corrosion before failure than rods with lower stress levels.

Corrosion inhibitors are less effective in sucker rod pumps because of wear. Corrosion-related failures are generally controlled by changing the pump metallurgy. Guidelines for selecting pump materials are provided in NACE MR0176 (Ref 101). Galvanic corrosion problems can be quite severe in pumps and are best controlled by eliminating or reducing the extent of dissimilar metals in contact with each other in the pump. This also applies to coatings used for wear resistance, such as chromium and nickel

plating. Rapid failure can often occur in underlying steel if these coatings become damaged by wear. If the wear resistance of chromium plating is required, it may be necessary to upgrade the base material to avoid galvanic corrosion problems.

Wear of sucker rod strings can be controlled through the use of centralizing rod guides. A variety of nonmetallic materials are either molded on or physically attached to the sucker rod to prevent it from contacting the tubing. Welded or metal guides should not be used. Sucker rod couplings are normally coated with a corrosion-resistant alloy by flame spraying or similar techniques. This will provide both wear and corrosion protection. Similar coatings can be applied to the rods; however, these have not been widely used because of the high cost involved.

Fiber-reinforced plastic sucker rods can be used to reduce corrosion fatigue failures; however, their primary benefit comes from production concerns rather than corrosion. Corrosion inhibition is still necessary when FRP rods are used to protect the steel end connectors of the rod and steel well tubulars. In addition, steel rods are not entirely eliminated from the string when FRP rods are used. Internal tubular coatings are not widely used in rod-pumped wells, because they rapidly fail from rod wear. Fiber-reinforced plastic tubing is not widely used for the same reason.

Electric submersible pump wells are treated in much the same way as rod-pumped wells. Electric submersible pump wells pose an additional problem in that the pump fluid intake is above the motor housing. This means that inhibitors injected into the annulus do not reach the housing. A variety of methods have been used to reduce the corrosion of housings, including applying corrosion-resistant coatings and selecting corrosion-resistant alloys for the housing. Special inhibitor-injection systems using small-diameter tubing to release inhibitors below the motor have also been employed. Corrosion of electric submersible pump internal parts is not typically a problem because of the widespread use of corrosion-resistant alloys. Internal tubular coatings can be used with electric submersible pump wells, because they are not subject to wear. Fiber-reinforced tubing has found application in a limited number of electric submersible pump wells.

Gas-lift wells are commonly treated by atomizing inhibitor solutions into the lift gas. This can provide protection to the tubulars only above the lowest operating gas-lift valve. Internal tubular coatings, FRP tubulars, and corrosion-resistant alloys can be used above or below the operating valve to provide corrosion protection.

Producing Flow Lines. Carryover from downhole corrosion inhibition is often sufficient to protect flow lines. In extremely corrosive conditions, additional inhibitor injection, either batch or continuous, may be required. Internal coatings can be used on flow lines; however, obtaining protection in the area of pipe joints can be difficult. A variety of methods have been

developed to minimize damage to the coating even in welded lines. Fiber-reinforced plastic line pipe is becoming more widely used for flow lines because it is inherently corrosion resistant. Polyethylene lines are also used in low-temperature low-pressure applications.

Oil/Water Separation Facilities. Supplemental inhibitor injection is often used to help protect these facilities. In addition, vessels such as separators are often internally coated. Organic coatings are normally used, but platings such as electroless nickel are also employed. Noble platings, such as electroless nickel, can cause severe galvanic corrosion of underlying steel if the coating is cracked or otherwise damaged. Internal cathodic protection with sacrificial anodes is also used in vessels. Internal baffles and other pieces can be fabricated from corrosion-resistant alloys. Corrosion-resistant alloy linings can also be used.

Heat-transfer surfaces and vessel bottoms should be periodically cleaned of scale and debris. Scale inhibitors should be used if continuous scale-deposition problems occur. Chromium-containing steels (2.25 to 12% Cr) can be used for heat-transfer surface in direct-fired heaters to reduce the possibility of creep rupture failures in applications subject to severe scale formation. However, these materials can be rapidly attacked in the presence of H_2S . High-nickel corrosion-resistant alloys can also be used to help prevent underdeposit corrosion problems.

Tanks/Water Storage. Internal coating is a common method of protecting tanks. Organic coatings are typically used. Steel tank life is often extended by the use of FRP linings, especially tank bottoms. Both chopped and mat systems are used. A variety of nonmetallic liners have also been used. Fiber-reinforced plastic tanks are becoming more popular in smaller sizes. Internal cathodic protection can also be used, normally in conjunction with internal coatings. Tanks should be periodically cleaned to remove the accumulated sludge and debris that hinder normal corrosion control methods and promote underdeposit and sulfate-reducing bacteria problems.

Tanks are usually the first source of oxygen contamination in the injection system. Open tanks and pits should be avoided. Various methods of excluding oxygen in open tanks have been attempted. Oil layers are ineffective. Several floating systems have been developed that are useful to some degree, but are not totally effective. It must be remembered that as little as 0.01 ppm oxygen is sufficient to cause major increases in corrosion rates. Oxygen also renders many corrosion inhibitors ineffective. Closed tanks can also allow oxygen entry. Poorly maintained hatch seals and venting systems are notorious as sources of contamination. The optional method of excluding oxygen is to ensure that all openings to the tank are properly maintained and that a low-pressure inert gas blanket is used. Gas blanketing provides a slight positive pressure that will keep air from entering. Gas blankets can be part of the vapors-recovery sys-

tem, if used, or can be externally supplied from bottled gases, such as nitrogen.

Oxygen can enter the injection system in other ways. Often, additional water must be obtained to augment produced water volumes. Freshwater can be obtained from lakes, rivers, or wells drilled into aquifers. Seawater is used in offshore and coastal locations. All of these waters will have some amount of oxygen contamination. Severe corrosion can result if this contamination is not removed. Common removal methods include the use of chemicals or scavengers, such as sodium sulfite or ammonium bisulfite, and vacuum or gas stripping (see the discussion "Environmental Control" in this article).

Tanks are also excellent locations for the growth of sulfate-reducing bacteria. If tanks become contaminated with sulfate-reducing bacteria, they must be cleaned and sterilized with biocides. Cleaning is a necessity, because it is impossible for biocides to adequately penetrate the large amounts of sludge and debris on the tank bottom.

Injection Pumps. Corrosion-resistant alloys are widely used in injection pumps and ancillary equipment. The particular choice of materials used will depend on the nature of the fluids handled and the type of pump involved. Specific material recommendations are provided in NACE RP0475 (Ref 102). Caution should be exercised, because this specification does not address the temperature limitations of the materials. Chloride SCC can occur in 300 series stainless steels if they are used in saline waters above 52 to 65 °C (125 to 150 °F). Also, pitting of these materials can occur in aerated saltwater if they are left stagnant in a pump. For example, it is common practice to have standby equipment piped into a system and to test the equipment periodically. Flushing the equipment with deaerated and inhibited freshwater is recommended to prevent pitting corrosion.

Flow Lines and Injection Wells. All potential corrosion mechanisms must be dealt with to obtain acceptable service lives of injection systems. This includes corrosion by dissolved acid gases, growth of sulfate-reducing bacteria, oxygen contamination, and scale/sludge deposition.

Corrosion inhibitors can be used to control flow-line and injection-well corrosion. Treatment is usually continuous, but batch treatment can also be used. Both oil-soluble/highly water-dispersible and water-soluble chemicals are used. Flow lines can be internally coated with organic coatings. Cement and other nonmetallic linings are also used. Fiber-reinforced plastic flow lines are widely used, even in high-pressure injection systems, under API standards for these types of tubular products.

Injection-well tubulars can be bare steel if corrosion inhibition is used. Internal coating is also widely used even with corrosion inhibition (see the discussion "Coatings" in this section). Care must be taken when handling internally coated tubing to prevent coating damage. Special guides must be used when the tubing is installed to prevent damage to the pin nose. Makeup

equipment must not deform the tubing enough to crack the coating. Standard API couplings are routinely internally coated in the standoff thread area. The recent advent of flush joint tubing connections using nonstandard couplings has helped to make internally coated tubing applications more reliable. The new connections help to seal the end of the tubing joints in the coupling. This has long been a problem area in internally coated tubing because it is easily damaged during handling and installation.

Corrosion-resistant alloy tubulars are used on some occasions, but their high cost is usually prohibitive. Fiber-reinforced tubing is used to some extent; however, again, the lack of standardization has been a limiting factor. Handling and makeup procedures are critical for successful fiber-reinforced tubing application. Many failures have resulted from overtightening of FRP connections by crews used to handling steel tubulars. No reliable method has been developed for accurately predicting the long-term performance of FRP tubulars subject to both internal pressure and axial load.

Injection wells frequently require acidizing to restore injectivity. Typical acids used are 15% HCl and 12% HCl-3% HF. Severe corrosion can result if these acids are not properly inhibited. Corrosion inhibitors are available from acid service companies. Inhibitor concentration should be such that the corrosion rate of low-carbon steel is less than 245 g/m² (0.05 lb/ft²) over the length of time the acid is to be in the well. It is good practice to ensure that the acid delivered to the job site actually contains the inhibitor and is the strength called for in the workover procedure. A simple test procedure for determining the presence or absence of inhibitor is given in NACE RPO273 (Ref 103). This test is not designed to determine inhibitor effectiveness at well conditions or to compare different inhibitors. Laboratory testing is necessary to establish inhibitor effectiveness.

Acid exposure can have a wide range of effects on the internal tubular coatings that may be present. Laboratory testing should be conducted if there is any doubt regarding the ability of the coating to withstand the acid exposure without damage. Fiber-reinforced plastic tubulars can also be damaged by exposure to mineral acids. Although tubing manufacturers do not prohibit acid exposure, they all recommend that temperatures and exposure times be kept to absolute minimums. The use of hydrofluoric acid in acidizing fluids is not recommended if FRP tubing is installed.

Carbon Dioxide Injection

Secondary recovery by waterflooding can greatly increase the amount of oil recovered over primary production, but may still leave up to 80% of oil in place in the reservoir. Tertiary recovery by injecting CO₂ will remove the oil not obtained by waterflooding. Carbon dioxide can be used at much lower pressures than other gases,

such as nitrogen or methane, because it dissolves readily in some crudes and can cause up to a tenfold viscosity reduction in heavy crudes.

Oils with an API gravity of 25 or higher are candidates for miscible flooding. This process can recover oil from low-permeability reservoirs. Oils with gravities down to API 15 are recovered by an immiscible process based on oil swelling and viscosity reduction.

Carbon dioxide injection uses gas from fields that produce almost pure CO₂ from burning of lignite and recovered CO₂ from industrial combustion gases. These gases are purified and compressed, and in some cases, there are pipelines for hundreds of miles to the fields to be flooded with CO₂. The Texas Permian Basin, North Dakota, the Texas Gulf Coast, and the California area have had CO₂ injection projects in operation since the 1980s.

Because CO₂ is an acid gas, production problems are encountered when CO₂ is injected. Carbon dioxide ionizes in water to form carbonic acid and will react directly with carbon steel. The corrosion rates can be quite high, and pumps can fail in a matter of days after breakthrough of the CO₂ into producing wells. Some scaling problems may arise because carbonic acid may dissolve calcium carbonate from the formation. The calcium bicarbonate formed during this reaction may come out of solution in heaters and vessels as calcium carbonate when CO₂ is lost. Calcium sulfate (CaSO₄) will also dissolve and may cause scaling in surface equipment.

Emulsion-treating characteristics may change when CO₂ dissolves in oil. Asphaltenes may cause problems by dissolving in CO₂ as it sweeps through the formation and then coming out of solution on the surface.

Elastomers must be selected with care, because they may swell or lose strength when exposed to CO₂. Leaking packers due to seal failure will cause pressure on the annulus of CO₂ injection wells and annular space corrosion.

Carbon Dioxide Production Facilities

Carbon dioxide source wells may produce from a few percent to almost pure CO₂. They may produce both liquid- and vapor-phase CO₂. The formation of liquid water in the produced CO₂ will cause hydrate formation and corrosion. Hydrate formation can be controlled by glycol dehydration, but special measures must be taken to control corrosion.

A corrosion inhibitor can be added to the producing well to control corrosion. Continuous injection downhole of a water-soluble or dispersible filming amine inhibitor should protect the tubing and wellhead. The use of type 316L and 304L stainless steels and FRP for completions and flow lines is an alternative to inhibitor use, presuming that substantial chlorides are not present that may adversely affect the performance of the stainless steel.

In a typical CO₂ production facility, the gas travels through a wellstream heater to a contactor

in which water is removed. It is then scrubbed, compressed, and sent to the pipeline. Materials selection in the design of the system is the key to corrosion control in the processing plant. Corrosion-resistant alloys can be used in areas of high corrosion, and carbon steel is used where conditions allow its use. A maximum water content of 60% of saturation at the minimum operating temperature is obtained by dehydration so that corrosion of the steel pipeline is prevented. Dehydration also prevents hydrate formation when temperatures are low.

Injection Systems

Water and CO₂ are injected alternately in some systems, such as the SACROC unit in the Kelly Snyder field in west Texas. This is known as the water alternate gas process.

The distribution system consists of parallel separate lines for water and CO₂ that are carbon steel coated externally and cathodically protected. Carbon dioxide in the line contains less than 50 ppm water, so internal corrosion is minimal. Valves in the system range from bare carbon steel to plastic coated with type 316 stainless steel trim. Fluorocarbon and nylon O-rings have performed satisfactorily, and Buna N rubber is used for stem sealing, although these materials swell somewhat.

Water lines are cement lined with sulfate-resistant cements and artificial pozzolans, as specified in API RP-10E (Ref 104). Most leaks have been due to the failure of asbestos gaskets. The use of grout instead of gaskets has been effective. Water-soluble inhibitors are added to protect voids in cement linings and plastic coatings.

Carbon dioxide injection systems have suffered corrosion problems when the mixing of water and CO₂ at each cycle of alternate CO₂/water injection occurs. Plastic coating and type 316 stainless steel trim, ceramic gate valves with electroless nickel-coated bodies, and electroless nickel-coated check valves were tried. The type 316 stainless steel and ceramic gates performed well, but the other methods failed.

Injection wells originally used type 410 stainless steel wellheads and valves. Severe pitting occurred under deposits laid down from suspended solids in the injection water. Type 410 stainless steel was plastic coated, and the gates and seats were changed to type 316 stainless steel to correct the problem.

Failures occurred in the couplings of the plastic-coated tubing in the injection wells when the seal rings failed. This was corrected by changing the coating on the couplings from an epoxy-modified phenolic to a polyphenylene sulfide.

Production Systems

Most failures in the SACROC unit were due to rod breakage. Inhibitor programs were satisfactory in some wells, but many did not respond.

Plastic-coated rods and thermal spray metal coating with type 316 stainless steel helped to alleviate the problem. The use of fiberglass rods in the upper 70% of the string, along with stainless steel coated rods on the bottom, reduced rod breakage to an average of 1.1 per well per year.

Tubing leaks can be controlled with coatings and the use of 9Cr-1Mo and 13% Cr steel tubing where inhibitors fail to control. Flow-line corrosion can be controlled by the use of fiberglass-epoxy lines. Other systems have experienced problems similar to those found in the SACROC unit and have successfully controlled corrosion with the previously described methods. Inhibitor selection by field testing with linear polarization techniques or similar techniques has resulted in improved protection of producing wells. The electrochemical corrosion monitoring is also used routinely, along with coupons, iron counts, and caliper surveys.

Corrosion of Oil and Gas Offshore Production Platforms

Offshore structures have been in service in various parts of the world for more than 50 years. Early experience was in the Gulf of Mexico with water depths of less than 90 m (300 ft). Technology has advanced to the point at which the largest drilling and production platform stands in more than 305 m (1000 ft) of water. Current technology for deep seawater applications now includes the use of subsea wellheads and manifolds and gathering systems that have extended offshore operations into water depths of more than 3000 m (9300 ft).

A platform consists of three parts. The jacket is a welded tubular space frame that is designed as a template for pile driving and as lateral bracing for the piles. The piles anchor the platform permanently to the sea floor and carry both vertical and lateral loads. The superstructure is mounted on top of the jacket and consists of the deck and trusses necessary to support operational and other loads. Generally, platforms are carried from the fabrication yard to the site on a barge and are either lifted or launched off the barge into the water. After positioning the jacket, the main piles are driven through the legs of the jacket, one through each leg. Other piles, known as skirt piles, can be driven around the perimeter of the jacket as needed.

Current design and fabrication practices related to fixed steel offshore structures can be found in industry publications, professional journals, and the proceedings of technical conferences. The most basic U.S. document on this subject is API RP-2A (Ref 105), which was first issued in Oct 1969 and has had many subsequent editions. Because U.S. experience has been mainly in the Gulf of Mexico, API RP-2A generally represents that experience. Since then, added experience in deeper waters has been obtained in the Gulf of Mexico, the North Sea, and the coastal waters of

Brazil and West Africa. This information can be obtained in recent conference proceedings and technical publications of Society of Petroleum Engineers (SPE), API, and NACE. An overview of new materials technology for corrosion prevention in deep water, oil, and gas operations is available in Ref 61. It includes a summary of these advances:

- Use of higher-strength steels and composite materials for construction of lighter platforms
- Use of thermal spray aluminum coatings for subsea components to supplement normal sacrificial anode cathodic protection systems
- Use of high-strength, corrosion-resistant alloy tubulars made from martensitic, duplex, and austenitic stainless alloys to reduce wall thickness and maximize load and pressure

Fig. 24 Corrosion zones on fixed offshore structures. Source: Ref 106

bearing capabilities, while eliminating corrosion inhibition

- Use of engineered materials systems such as flexible pipe and umbilicals that incorporate a variety of materials (alloys, plastics, and composites) with unique designs to allow features not possible with monolithic metallic construction

General Corrosion

Marine structures operate in a complex environment that can vary significantly according to site location and water depth. Figure 24 shows the four main platform corrosion zones: soil, seawater, splash zone, and marine atmospheric. Recently, studies have shown that deep seawater conditions also pose their own unique conditions that are different from normal marine service under shallower conditions.

Marine atmospheric corrosion problems occur on the portion of the jacket above the splash zone and on the superstructure. Exposed steel surfaces

Fig. 25 Zones of corrosion for steel in seawater and the relative corrosion rate in each zone. Source: Ref 108

suffer corrosion from an environment of water condensation, rain, salt precipitation, sea mist, and oxygen. Corrosion rates can range from 0.05 to 0.64 mm/yr (2 to 25 mils/yr). Corrosion is particularly severe at crevices and sharp-edged areas, such as skip-welded plates and steel structural shapes. Attention to design and fabrication details can eliminate most of these problem areas. Atmospheric corrosion can be minimized by using coatings or by substituting nonferrous materials, such as copper alloys, nickel alloys, and FRP for steel components. Care must be taken to not create a galvanic-corrosion problem by coupling dissimilar metals. Table 10 gives a summary description of several marine zones and the characteristic corrosion behavior of the steel.

The splash zone is defined in NACE RP0176 (Ref 108) to be the area of the platform that is alternately in and out of the water because of tides, winds, and sea. It does not include surfaces that are only wetted during major storms. The splash zone of the platform can cover an interval of 1.5 to more than 12 m (5 to more than 40 ft), depending on location. Generally, the area of the platform that suffers the most severe steel corrosion is the splash zone, as shown in Fig. 25. Common methods of controlling corrosion in the splash zone include applying coatings, increasing jacket wall thickness by 6.4 to 19 mm (0.25 to 0.75 in.) in the splash zone to compensate for the higher corrosion rates, or applying a Monel alloy wrapper.

Corrosion of steel in seawater is a function of water salinity, temperature, oxygen content, velocity, resistivity, and chemistry. Table 11 summarizes the effects of these and other factors on the corrosion of steel in seawater. Several of the variables controlling corrosion are inter-related. As an example, Table 12 demonstrates

Table 10 Classification of typical marine environments

Marine zone	Description of environment	Characteristic corrosion behavior of steel
Atmosphere (above splash)	Minute particles of sea salt are carried by wind. Corrosivity varies with height above water, wind velocity and direction, dew cycle, rainfall, temperature, solar radiation, dust, season, and pollution. Even bird droppings are a factor.	Sheltered surfaces may deteriorate more rapidly than those boldly exposed. Top surfaces may be washed free of salt by rain. Coral dust combined with salt seems to be particularly corrosive to steel equipment. Corrosion usually decreases rapidly as one goes inland.
Splash	Wet, well-aerated surface; no fouling	Most aggressive zone for many metals, for example, steel. Protective coatings are more difficult to maintain than in other zones.
Tidal	Marine fouling is apt to be present to high watermark. Oil coating from polluted harbor water may be present. Usually, ample oxygen is available.	Steel at the tidal zone may act cathodically (well aerated) and receive some protection from the corrosion just below tidal zone in the case of a continuous steel pile. Isolated steel panels show relatively high attack in the tidal zone. Oil coating on surface may reduce attack.
Shallow water (near surface and near shore)	Seawater usually is saturated with oxygen. Pollution, sediment, fouling, velocity, and so on, all may play an active role.	Corrosion may be more rapid than in marine atmosphere. A calcareous scale forms at cathodic areas. Protective coatings and/or cathodic protection can be used for corrosion control. In most waters, a layer of hard shell and other biofouling restricts the available oxygen at the surface and thus reduces corrosion (increased stress on structure from the weight of fouling must be provided for).
Continental-shelf depths	No plant fouling, much less animal (shell) fouling with distance from shore. Some decrease in oxygen, especially in the Pacific, and lower temperature	...
Deep ocean	Oxygen varies, tending to be much lower than at the surface in the Pacific but not too different in the Atlantic. Temperature near 0 °C (32 °F). Velocity low; pH lower than at surface.	Steel corrosion is often lower. Anode consumption is greater to polarize the same area of steel as at the surface. There is less tendency for protective mineral scale formation.
Mud	Bacteria are often present, for example, sulfate-reducing types. Bottom sediments vary in origin, characteristics, and behavior.	Mud is usually corrosive, occasionally inert. Mud-to-bottom water corrosion cells seem possible. Partly embedded panels tend to be rapidly attacked in mud. Sulfides are a factor. Less current than in seawater is consumed to obtain cathodic polarization for the buried part of the structure.

Source: Ref 107

the relationship between temperature and oxygen solubility in seawater. Generally, the lower the seawater temperature, the higher the gas solubility observed; however, action of currents and mixing of shallow and deep water can also have an effect. As temperature or oxygen levels increase, corrosion rates will increase. The interplay of seawater variables is different for different locations. An example of this is shown in Fig. 26 (Ref 63). These conditions will determine the aggressivity of the service and, in turn, the demands on the cathodic protection system and/or coatings. To control seawater corrosion, the steel jackets are normally cathodically protected. The types of cathodic protection systems used are sacrificial anode, impressed current, or a combination of the two (see the discussion "Cathodic Protection" in this article). Occasionally, cathodic protection will be used in combination with coatings. Not only does cathodic protection control corrosion, but it also eliminates concern over corrosion fatigue failure of the jacket. Corrosion fatigue is discussed in more detail below. Typical cathodic protection system design parameters are given in Table 13 to 15.

The major platform components below the mudline are the jacket piles. In general, steel corrosion rates are low below the mudline. The exception is when the mud contains sulfate-reducing bacteria. Because the piles have elec-

trical continuity with the jacket, the cathodic protection system will normally protect the piles from corrosion in saline muds.

Fatigue

Corrosion is of particular concern for the platform tubular welded joints, called nodes. The nodes are areas of high stress due to their complex geometries (Ref 110–112). The points of maximum stress in the nodes occur at the toe of the welds joining the tubular members. Cyclic stresses result from environmental factors, such as waves, tides, and operating loads. Platforms are designed to handle both a maximum stress and fatigue. The maximum stress is usually based on 100-year storm conditions. Platform fatigue life is based on an environmental stress distribution analysis, along with analysis of the stress cycles (Ref 113). Fatigue design curves have been published by the American Welding Society, British Standards Institute, API, and Det Norske Veritas.

Corrosion can reduce the fatigue life of platform anodes. Galvanic corrosion of non-stress-relieved welds and pitting corrosion can result in stress raisers. Therefore, corrosion can lead to the initiation of cracks and can increase the growth rate of existing cracks, reducing fatigue life. The fatigue life of steel exposed to seawater is shorter than that of steel exposed to air because

of corrosion fatigue. As Fig. 27 illustrates, steel immersed in seawater does not exhibit an endurance limit. Because there is no endurance limit, unprotected steel exposed to seawater is susceptible to fatigue failure even at low stress levels after long-term cyclic service. An API study discussed crack initiation in smooth, notched, and welded specimens and summarized a number of earlier investigations (Ref 115). Table 16 ranks according to importance the various seawater environmental variables influencing corrosion fatigue crack initiation of carbon steel. The corrosion fatigue effects are eliminated by the application of cathodic protection (Fig. 28).

Inspection

The purpose of periodic inspection is to ensure that the structure is fit for continued service. Through the inspection program, a company is protecting its personnel and its equipment. In some locations of the world, governmental bodies have established legislation or code agencies that determine minimum inspection requirements. Elsewhere, the operator decides on the minimum inspection needs for the platform. Detailed information on inspection procedures can be found in the article "Inspection, Data Collection, and Management" in this Volume.

Inspection is required even though platforms are designed and constructed to conservative codes (Ref 116). Inspection allows confirmation that the codes are adequate. It should be noted that the codes represent the best experience and knowledge at the time they are written. Often, the design parameters must be extrapolated for use in new frontier environments that were not foreseen when the codes were written. Inspection results provide the information necessary for updating the codes to account for these new environments. Inspection of the platform jacket is designed to assess corrosion, fatigue cracks, joint and brace failure, impact damage, marine growth, scour, and debris accumulation. Inspection techniques include visual inspection by divers and remote operated vehicles, still and video photography, ultrasonic thickness measurements, cathodic potential surveys, magnetic-particle inspection, and vibration frequency attenuation.

Table 11 Factors that affect corrosion of carbon steel immersed in seawater

Factor	Effect on iron and steel
Chloride ion	Highly corrosive to ferrous metals. Carbon steel and common ferrous metals cannot be passivated. Sea salt is about 55% chloride.
Electrical conductivity	High conductivity makes it possible for anodes and cathodes to operate over long distances; therefore, corrosion possibilities increase, and the total attack may be much greater than that for the same structure in freshwater.
Oxygen	Steel corrosion is cathodically controlled for the most part. Oxygen, by depolarizing the cathode, facilitates the attack; therefore, a high oxygen content increases corrosivity.
Velocity	Corrosion rate is increased, especially in turbulent flow. Moving seawater may destroy the rust barrier and provide more oxygen. Impingement attack tends to promote rapid penetration. Cavitation damage exposes fresh steel surfaces to further corrosion.
Temperature	Increased ambient temperature tends to accelerate attack. Heated seawater may deposit protective scale or lose its oxygen; either or both actions tend to reduce attack.
Biofouling	Hard-shell animal fouling tends to reduce attack by restricting access of oxygen. Bacteria can take part in the corrosion reaction in some cases.
Stress	Cyclic stress sometimes accelerates failure of a corroding steel member. Tensile stresses near yield also promote failure in special situations.
Pollution	Sulfides, which are normally present in polluted seawater, greatly accelerate attack on steel. However, the low oxygen content of polluted water could favor reduced corrosion.
Silt and suspended sediment	Erosion of the steel surface by suspended matter in the flowing seawater greatly increases the tendency toward corrosion.
Film formation	A coating of rust or rust and mineral scale (calcium and magnesium salts) will interfere with the diffusion of oxygen to the cathode surface, thus slowing the attack.

Corrosion of Gathering Systems, Tanks, and Pipelines

Gathering systems are defined as all production facilities from the wellhead choke (or pumping T) to the sales point (oil and/or gas); subsystems include flow lines, separation, and dehydration. Gas processing is reviewed briefly. Sulfur plants (conversion of H_2S to elemental sulfur), gas transmission lines and oil pipelines, gasoline plants, and water-handling facilities for disposal are beyond the scope of this discussion,

although the same principles will apply. Internal and external corrosion alleviation systems are reviewed, respectively.

Internal corrosion is dependent on the composition, temperature, pressure, and flow regime of the produced fluids. For many years, it was felt

that the general direction of the effect of each of these variables was known, but the magnitude of the effect was not precisely known. More recently, computer software has made it possible to model these system more precisely and take into account many of these variables to predict the effects of flow and corrosion.

A natural gas reservoir is a reservoir that, under initial conditions, is a single, gaseous hydrocarbon phase. If this gaseous phase contains hydrocarbons that are recoverable as liquids on the surface, the reservoir is a gas condensate reservoir. A gas well is a well that produces fluids from a gas or gas condensate reservoir. An oil well is a well that produces from a hydrocarbon reservoir that is either a two-phase system or a single liquid phase (Ref 117). A general distinction between the two is commonly based on gas-to-oil ratio (GOR). Wells with a GOR greater than 890 m³/m³ (5000/mmscf) are commonly considered gas wells. Wells with lower GOR values are referred to as oil wells due to the predominance of liquid hydrocarbons. Because many liquid hydrocarbons often have some ability to form a protective layer on steel and displace water, corrosion problems are generally considered greater in gas wells than in oil wells. Because produced fluids essentially determine the internal environment (weather conditions and process design can affect temperatures and pressures), gathering systems for gas wells and oil wells are discussed separately.

From both a metallurgical and corrosion viewpoint, it is important to distinguish between sweet gas wells and sour gas wells. If the partial pressure of H₂S is greater than 0.34 kPa (0.05 psia), the gas stream is generally considered sour and materials that resist sulfide stress cracking must be used. However, the latest revision of NACE MR0175/ISO 15156 (Ref 14) lists materials that are recognized to have acceptable resistance to sulfide stress cracking. In this standard, it is indicated that H₂S partial pressure must be considered in combination with pH, which can vary with the partial pressure of acid gases (CO₂ and H₂S) and buffering salts in the water phase such as bicarbonate. Therefore, the higher the pH, the more H₂S can be tolerated before critical levels are reached. This document also indicates that the level of chlorides in the produced water can also influence the corrosivity and susceptibility to sulfide stress cracking. The sour-service serviceability chart per the NACE MR0175/ISO 15156 is given in Fig. 29. It shows various regions of varying severity relative to the need to select materials resistant to sulfide stress cracking and where testing of materials may be needed.

The determination of whether H₂S or CO₂ corrosion mechanisms will predominate is not as simple. Early investigators believed that CO₂ had a synergistic effect on H₂S corrosion. Subsequent investigators indicated that it is the ratio of partial pressures of CO₂ to H₂S that controls the corrosion mechanism. Unless the ratio of CO₂ to H₂S partial pressure is greater than 500, the corrosion mechanism is normally dominated

Table 13 Design criteria for offshore cathodic protection systems

Production area	Environmental factors(b)					Typical design current density(c)	
	Water resistivity, Ω · cm(a)	Water temperature		Turbulence factor (wave action)	Lateral water flow	mA/m ²	mA/ft ²
		°C	°F				
Gulf of Mexico	20	22	70	Moderate	Moderate	54–65	5–6
U.S. West Coast	24	15	60	Moderate	Moderate	76–106	7–10
Cook Inlet	50	1	35	Low	High	380–430	35–40
North Sea(d)	26–33	0–12	32–55	High	Moderate	86–216	8–20
Persian Gulf	15	30	85	Moderate	Low	54–86	5–6
Indonesia	19	24	75	Moderate	Moderate	54–65	5–6

(a) Water resistivity is a function of chlorinity and temperature, and it decreases as both chlorinity and temperature increase. (b) Typical values and ratings based on average conditions, remote from river discharge. (c) In ordinary seawater, a current density less than the design value will suffice to hold the platform at protective potential once polarization has been accomplished and calcareous coatings are built up by the design current density. It should be noted, however, that depolarization can result from storm action. (d) Conditions in the North Sea can vary greatly from the northern to the southern area, from winter to summer, and during storm periods. Source: Ref 108

by H₂S (Ref 118). More recent investigations suggest that there may also be an effect of temperatures on the ratio of CO₂ to H₂S partial pressure (Ref 119).

Because CO₂ corrosion is usually more severe (i.e., higher corrosion rates) than experienced for H₂S corrosion at lower temperature conditions, and because most production facilities are relatively cool (<60 °C, or 140 °F), CO₂ corrosion should be considered whenever the ratios of CO₂ to H₂S partial pressures are greater than 200. Oxygen is not present naturally in oil and gas reservoirs, and without exception it is preferable to keep it out since it results in still higher corrosion rates and increased tendency for localized corrosion. The biggest threats to oxygen ingress come in handling production environments due to injection of aerated chemicals (hydrate control fluids, drilling and packer fluids, and corrosion and scale inhibitors), suction leakage in pumps, and backstreaming of oxygen through leaky valves in pressure-containing equipment.

Sweet Gas

With regard to CO₂ corrosion alleviation in flow lines, there are several choices. First, low-alloy steel with a corrosion allowance can be used; a nomograph establishes the maximum corrosion rate for CO₂ (Ref 120) or, more recently, corrosion modeling software can be used to more accurately predict the severity of corrosion (Ref 29). Velocity may also be important; several authors have suggested that there is a critical velocity (or more accurately, flow-induced wall shear stress) above which CO₂ corrosion is very difficult to control (Ref 41, 121). Again, more recent data suggest that at the same temperature, pressure, fluid composition, and pH, the CO₂ corrosion-velocity relationship is a continuous relationship rather than a step function (Ref 119); however, for multiphase flow situations, discontinuous increases in flow-induced wall shear stress can occur as a result in changing flow regimes (e.g., slug flow, droplet

impingement) related to varying flow rate, liquid/gas ratio, and system geometry. If the flow lines are welded, the operator should be certain that the weldments are at least as corrosion resistant (and where H₂S is present, as cracking resistant) as the pipe body.

A second choice is to use corrosion-resistant materials, alloys, or coatings. With regard to CO₂, either type 316 stainless steel or duplex stainless steel will provide sufficient internal corrosion resistance. If H₂S is present, then NACE MR0175/ISO 15156 should be followed. Many types of stainless steels are subject to chloride SCC at elevated temperatures, and both alloys (type 316 stainless steel and duplex) may be subject to internal and/or external pitting corrosion, crevice corrosion, or SCC. Both alloys also require special care from the time they are installed to the time they are put into service. Oxygen and perhaps bacteria will result in pitting corrosion, depending on how the material is stored prior to installation or following hydrostatic testing before being put into service. Partially aerated hydrostatic test water (fresh water or seawater) is very aggressive to both steels and stainless alloys. Metallurgical solutions, if properly executed, can result in permanent, low-maintenance corrosion alleviation systems. However, this often requires anticipation of the relevant worst-case scenario that may occur during the service life of the systems, which is not necessary at the beginning of service. Increases in water content, reservoir souring, and other factors can dictate long-term performance of materials of construction.

A third choice is to insert an internal liner in low-alloy steel pipelines with a corrosion-resistant material. These systems may have advantages over solid corrosion-resistant alloys. First, they may be less expensive, and second, the alleviation of external corrosion problems of low-alloy steel is well understood (years of history with large quantities of pipelines) and less sophisticated. There are two disadvantages. Special welding procedures are required, and when the metallurgical coating is not bonded, buckling of the liner may occur, particularly in bends. This buckling will inhibit the use of tools pumped through the flow line.

Two other types of internal barriers are also commonly used: organic polymers (plastic coatings) and cement linings. Both systems can be economic successes. However, both systems

Table 14 Energy capabilities and consumption rates of sacrificial anode materials in seawater

Anode material	Energy capability(a)		Consumption rate		Anode to water(b) closed circuit potential, V versus Ag/AgCl reference electrode
	A · h/kg	A · h/lb	kg/A · yr	lb/A · yr

Fig. 27 Fatigue data for carbon steel in seawater as a function of specimen potential. Source: Ref 114

Table 16 Summary of major variables influencing the corrosion fatigue crack initiation behavior of carbon steels in seawater

Variable	Effect
Cyclic frequency	Slower frequencies cause reduced fatigue resistance for unprotected steel.
Cathodic potential	Adequate cathodic protection restores fatigue resistance to levels observed in air.
Oxygen level	Fatigue resistance in deaerated seawater is similar to that in air.
Temperature	Although decreasing temperature results in increased oxygen levels, the overall effect of decreasing temperature is that fatigue resistance is improved to some extent in range of 13 to 45 °C (55 to 115 °F).
pH level	Over a broad range of values (4 to 10), there is little effect of pH on fatigue resistance. Low values (<4) decrease fatigue resistance, and high values (>10) improve fatigue resistance to levels similar to those observed in air.

Source: Ref 115

have difficulty in maintaining corrosion resistance at the joints, are difficult to install holiday-free, have limited life, and may suffer disbondment and failure when the pipe is improperly handled or distorted. The plastic coatings are permeable to the produced fluids, and eventually (3 to 5 years or longer) the corrosive fluids will permeate the coating. The resulting corrosion products cause disbonding of the coating and complete loss of its corrosion resistance. Cement linings are thicker and less subject to produced fluid penetration than plastic coatings. They are heavy and may have limited resistance to acids.

A final alternative is to use nonmetallic pipe materials such as FRP or polymerized hydrocarbons. The advantage of these materials is their complete resistance to corrosion. Their disadvantages are low allowable temperatures, low fatigue resistance, low strength, low resistance to mechanical damage, and high combustibility. They also have problems with joint integrity, although much work has been done recently to improve these systems. Finally, they may be vulnerable to chemical attack from the produced fluids (CO_2 may dissolve the resins from fiberglass pipe, and unsaturated hydrocarbons may dissolve the polymerized hydrocarbon pipes) and from chemicals that may be injected during workovers.

The most common alternative to corrosion-resistant materials is to use steel with corrosion inhibition. If corrosion inhibition is used to protect the gas well downhole tubulars, the same formulations can often protect the downstream flow lines if the flow lines are properly designed. Inhibitors should be evaluated for performance under downhole and flow-line conditions to ensure adequate performance. The flow lines should be sized to ensure turbulent flow (and mixing and coverage with inhibitor) at a velocity

that is not significantly higher than that present in the tubing. More inhibitor treatments fail in flow-line conditions due to lower than anticipated flow velocities than fail at high velocity. This often occurs when production rates decline with the age of the reservoir or from initial overdesign. Turbulent flow will ensure inhibitor contact with the entire internal pipe surface, and limited velocities (flow lines are cooler than gas well tubulars) will ensure that flow-line conditions are not significantly more corrosive than the gas well tubulars. Because of the economic consequences of downhole tubular failures (usually much greater cost than flow-line failures), designing the surface flow lines to utilize downhole inhibition systems effectively will result in a successful flow-line inhibition system. If a downhole inhibition system is not used (either from temperatures above the dew point or use of corrosion-resistant alloys), then surface inhibition can be used to protect the flow lines. In low-velocity/low-liquid flow regimes, periodic inhibition with a technique that inhibits the entire internal surface can be successful. This often involves the use of pigging to push retained water and fluids through the flow line and to redistribute inhibitors to all internal surfaces of the flow line. For higher velocities (turbulent flow) and/or high liquid content, continuous inhibition will probably be necessary. For extreme cases, special inhibitor formulations are available that have high reaction times and that can be retained on the metal surface even under very high flow-induced wall shear stress conditions.

Separation and dehydration facilities offer fewer alternatives. Because inhibitors usually stay in the liquid phase in multiphase systems and usually in the hydrocarbon phase if one is present, reliable inhibition of the vapor space is not usually possible, but vapor-phase inhibitors

can be used in some cases. Fortunately, corrosion is usually not severe, because only water of condensation is present. However, in cases which have high CO_2 partial pressures, this condition can produce low pH and high corrosion rates along with a high propensity for localized corrosion. For very severely corrosive environments, such as wet CO_2 , type 316 stainless steel or type 316 stainless steel internal cladding is usually used at less than 60°C (140°F); at higher temperatures, higher alloy stainless steels or alloy 825 clad steel is often used. For normal gas production with CO_2 , low-alloy steel, combined with a corrosion allowance, inhibitors, and monitoring, is often the most economic solution.

For gas dehydration systems, low-alloy steel with corrosion allowance is normally sufficient when combined with pH control of the glycol. For gas streams high in CO_2 concentrations, some operators have found it necessary to internally clad the wet gas portions with type 316 stainless steel or higher alloys depending on temperature, environmental severity, and anticipated service life.

Sour Gas

Sour gas wells present a more difficult problem. First, all materials must be resistant to sulfide stress cracking. It is essential that no equipment suffer catastrophic cracking failures that impair pressure containment or operability of the component. General corrosion is often less severe for H_2S than for CO_2 at the lower temperatures usually encountered in flow-line systems, and H_2S corrosion is not usually as velocity dependent. As long as sufficient liquid hydrocarbon is present, corrosion is usually minor. When hydrocarbon liquids exceeds 100 barrels per $28,300\text{ m}^3$ ($1 \times 10^6\text{ ft}^3$) of gas, when the water content of the liquid phase is less than 10%, and when the flow is turbulent (to avoid water phase in the bottom of the line), corrosion problems are often self-mitigating, resulting in acceptable corrosion rates. In cases in which the

Fig. 28 Effect of cathodic protection on the fatigue performance of alloy steel in seawater. Tests performed on 6.4 mm ($1/4$ in.) diam specimens at a mean stress of 425 MPa (69 ksi)

Fig. 29 Regions of increasing sour-service severity (0, 1, 2, 3) on a plot of pH and H_2S partial pressure. Source: Ref 14

above conservative criteria are not met, inhibition may be necessary. The same rationale in regard to the use of inhibitors in flow lines with CO₂ applies to flow lines for H₂S. Inhibition systems that protect downhole tubulars will protect the flow lines if the entire internal wall is inhibited (i.e., the flow line is in mild turbulent flow). Processing facilities, gas separators, and sweetening systems (sulfinol, amines, and so on) are usually constructed of low-alloy steel with a corrosion allowance and are regularly monitored. However, for longer-term project life, stainless alloys are finding more widespread use.

Oil Wells

Oil wells, as previously defined, are wells that produce from a hydrocarbon reservoir that is either two-phase or a single liquid phase. Oil-well flow-line corrosion is much easier to handle than gas-well flow-line corrosion. First, low-pressure sour oil wells are usually beyond the scope of NACE MR0175/ISO 15156. Second, CO₂ corrosion is seldom, if ever, a problem. Most crude oils (and associated gas) either contain no CO₂ or sufficient H₂S for H₂S to be the controlling corrosion mechanism. Corrosion problems are often minor until water cuts approach 30%. This rule assumes that the oil has some tendency to preferentially wet the metal surface, thus excluding water, and usually works for crude oil systems. For lighter hydrocarbon condensates, critical water cuts can be much lower, and in extreme cases be less than 10%.

Normally, when water cuts are high enough for saltwater corrosion (with or without H₂S) to be a problem in the flow lines, corrosion will also be more severe on the downhole tubulars. In this case, the inhibition system protecting the tubulars should also be designed to protect the flow lines. Flow lines with stratified flow that allow free water to flow or stagnate in the bottom of the flow lines may suffer corrosion problems. In these cases, inhibitors in the oil phase from the well may not help. This problem is successfully handled by frequent pigging in order to clear the flow lines of water; to clean out sediment, which will foster crevice corrosion; and to distribute inhibitor over the entire internal surface.

Gas separation facilities and free-water knockouts are usually made of low-alloy steel. Free-water knockouts are often internally coated with an organic coating. Coatings, if properly applied to clean, dry surfaces, may extend the vessel life a few years. Generally, coatings are not normally holiday-free, and therefore inhibitor may also be required. The only other alternative to low-alloy steel with corrosion allowance and internal coating is a corrosion-resistant material. The low corrosivity, however, does not normally justify the cost of a corrosion-resistant alloy, either solid or internally clad, unless the project is offshore, involves high production rates, or requires long-term service life. The combination of size and pressure

usually eliminates the use of materials such as fiberglass for these applications.

Corrosion problems can be severe in salt-water-handling facilities, although they are usually mild to moderate, often due to the exclusion of oxygen. Corrosion alleviation systems are limited to cathodic protection, organic coatings, and, occasionally, nonmetallic vessels.

Crude oil is usually dehydrated by using gravity separation of the lighter oil from the unwanted water. Heat, chemicals, and electric fields are often used to accelerate the gravity separation. The separation vessel should not experience severe corrosion if the system is kept oxygen-free. Cathodic protection is only partially successful for the vessel, because only the water-wet portion is protected and the oil/water interface fluctuates. The heating coils often suffer more severe corrosion than the vessel body. As long as these coils are in the water portion of the vessel and well designed to minimize local boiling and flashing, then maintained cathodic protection systems will be successful in alleviating corrosion of the heating surfaces. When large tanks are used, galvanizing significantly prolongs the tank life in the absence of H₂S. Hot-dip galvanizing is considered to be the most effective treatment, but it is limited to bolted tanks. The bolted tank gaskets, in turn, limit the temperatures at which the vessel can be operated.

The gas separated from the oil is low pressure and can be safely handled with low-alloy steel with a corrosion allowance. The storage of dehydrated oil (usually about 1% H₂O) poses no internal corrosion problems, except in the tank bottom, where saltwater will accumulate.

External Corrosion

External corrosion can also be a serious and costly problem. In wet or corrosive soil, low-alloy steel flow lines should be coated. There are a variety of successful coating systems. Usually, the external coating system consists of two parts: a mastic that coats and protects the pipe and a coating or wrapping that protects the mastic. Alternatively, epoxy coatings and extruded polyethylene and/or polypropylene coatings are used for more severe conditions and higher temperatures. If the flow lines are needed for long periods of time, then the external coating should be supplemented with cathodic protection. Surprisingly, it is probably more important to cathodically protect corrosion-resistant alloy flow lines than low-alloy steel flow lines. The corrosion-resistant alloys—type 316 stainless steel or duplex stainless steel—are subject to crevice corrosion and sometimes SCC in the presence of oxygen and chlorides, which are common in many areas, particularly in offshore areas. Because the stainless steel lines are much more expensive than low-alloy steel lines, they cannot be allowed to fail by external corrosion. Therefore, external cathodic protection of these flow lines is essential when they are buried or submerged. To reduce the current level required

for protection, the corrosion-resistant alloy, like the low-alloy steel pipeline, is usually externally coated. Recently, there has been concerns for overprotection that can result in hydrogen embrittlement of martensitic or duplex stainless steels particularly in the area of girth welds.

The other components of the gathering system are the storage tanks, gun barrels, and surge tanks. These vessels all internally accumulate saltwater on the bottom. Similarly, these tank bottoms are all subject to external corrosion. Because the tank bottoms are relatively thin and may suffer internal corrosion, they should be protected from external corrosion to maximize service life. Therefore, in wet environments or where long service is needed, cathodic protection of tank bottoms should be considered. For piping and vessels above ground, painting is the accepted method of protecting against corrosion.

Monitoring and Inspection

Monitoring is an essential part of any corrosion alleviation system. No corrosion alleviation system is completely reliable, and in many cases failure can be catastrophic, both from a personal safety perspective and from an environmental and/or economic perspective. There are a wide variety of monitoring inspection techniques. The thoroughness and frequency of the monitoring must be weighed against the consequences of failure, and the type of monitoring must be tailored to the particular system. Certainly, it is more catastrophic to have a high-pressure sour gas vessel failure than an atmospheric saltwater tank failure. However, in large, long-term projects, either failure can result in substantial lost production, if not monitored on a regular basis at the most critical locations.

Flow lines can be monitored with calipers that are pumped through the line, x-rayed, or, where warranted, cut open and inspected. Vessels can be visually and/or ultrasonically inspected. When ultrasonic inspection is used, reference points are usually permanently fixed to the vessel external wall so that the ultrasonic test is conducted at the same location each time. These are basically the methods used to find corrosion after it may have already occurred. Corrosion monitoring should be conducted in a manner where the results can be used as a process-control tool. Real-time corrosion monitoring can show the advance indications of corrosion and/or pitting before substantial corrosion actually takes place. Corrosion data can also be taken with process data to indicate the source of the problem and the root cause of the upset conditions that, if left unattended, will result in cumulative damage.

Storage of Tubular Goods

Tubular goods used in oil-producing and drilling operations are sometimes stored outdoors or in areas where internal storage is conducive to corrosion. This is particularly true in

coastal regions and industrial areas in which acid gases and pollutants are present as well as in oil fields that produce hydrogen sulfide.

Oxygen corrosion, or rust, is aggravated by the deposition of salt from marine environments, such as that encountered in wind-driven spray on offshore platforms, and airborne salt in coastal areas. Pipe yards situated close to the beach are particularly susceptible to severe atmospheric corrosion. In warehouses and under sheds, the presence of industrial pollutants such as SO₂, oxides of nitrogen, and other gases will initiate corrosion attack and increase rusting when they react with moisture in the air or on the pipe.

Even in areas of relatively low salt and pollutants content, severe corrosion may occur if the relative humidity is high. The pipe will cool off during the night, and dew will fall, covering the pipe with a conductive layer of electrolyte. The rust that is already on the pipe is hygroscopic and will remain moist after the free water has evaporated. This leads to concentration-cell attack and severe pitting. Pit depth and size are of particular importance, because failures may occur when the pipe is put into service under pressure.

Inspection

Before being put into service, tubular goods that have been stored for any length of time should be inspected. Particular attention should be given to:

- **External rusting:** The percent of surface area covered by rust should be recorded.
- **Presence of mill scale, lacquer-type mill coatings, or other temporary coatings:** This is important, because areas not covered may corrode, while protected areas may set up concentration cells and accelerate localized corrosion.
- **Internal corrosion:** The interior of the pipe should be inspected for rusting and pitting.
- **Condition of threads:** Threads should be examined to determine if corrosion damage has occurred that could prevent proper makeup.

Cleaning

After inspection, the pipe should be cleaned prior to applying any protective coatings. The pipe can be cleaned mechanically or with acids or rust dissolvers.

If the pipe is used, or has been stored in marine or industrial environments, it should be water blasted to remove any salt or acid deposits, weathered for a period of time to allow under-deposit salts to migrate to the surface, and water blasted again. One month is usually sufficient weathering time.

A water-soluble phosphate-base temporary rust inhibitor can be applied during the weathering period to minimize further rusting. The inside of the pipe should also be protected because water may collect on the bottom and cause pitting.

The pipe can now be physically cleaned. Wire brushing with an automated machine is a preferred method, but a rotary handheld wire brush can be used if a machine is not available. If rusting and pitting are severe, the pipe should be sand blasted. The inside of the pipe can be cleaned with a mechanical rattler or a round brush.

An alternative cleaning method for lightly rusted pipe or where mechanical cleaning facilities are unavailable is the use of an acid-base rust remover/chelant. These are usually based on phosphoric acid and will contain inhibitors and passivators to prevent removal of metal. The pipe can be soaked in a trough of the inhibited acid cleaner until deposits are dissolved.

Application of Protective Coatings

Once the pipe is cleaned, temporary rust-preventive coatings can be applied to halt further rusting. They can be applied by the automatic machine that cleans the pipe or by hand sprayers, dipping, or brushing. The important factor is that the pipe is completely covered with the coating. Temporary coatings are manufactured in several types, as discussed in the paragraphs that follow.

Lacquer coatings may consist of an oil-soluble resin in a volatile hydrocarbon solvent. These coatings may be brittle and may flake off and expose bare metal.

Slushing compounds usually consist of asphalt dissolved in a nonevaporating hydrocarbon so that a thick, oily layer is present on the surface. These compounds are resistant to mechanical damage, but may be difficult to apply and remove.

Polymeric coatings may contain acrylics, chlorinated vinyl chlorides, or other materials that will dry and polymerize from an aqueous solution. These coatings may contain metal passivators and rust converters that will be anodic to the metal surface and greatly alleviate further rusting. Polymeric coatings are easy to apply and are sometimes used without precleaning the surface, because the converters and passivators are design to modify corrosion by-products to eliminate concentration-cell corrosion.

Sulfonate-base coatings are formulated from petroleum sulfonates, waxes, and materials that form a flexible and nondrying coating. Pigments and fillers can be added for appearance and durability. The sulfonate acts as a rust inhibitor, and the other materials seal the surface to prevent moisture entry. These are relatively easy to apply and are resistant to mechanical damage.

Rust passivators are of the same type as the phosphoric acid base rust removers or may be similar to the polymeric coatings. They are used for rust prevention under sheds or in warehouses and may not be adequate for outdoor storage in corrosive areas.

The application method used will depend on the type of coating selected. A hydrocarbon-base coating can be brushed or sprayed, or the pipe can be dipped in a trough containing the

coating. Dilution with naphtha, aromatic solvents, or diesel oil can be done, depending on the recommendations of the manufacturer. A hydrocarbon-base coating should not be applied to wet or damp pipe. Some coatings are reported to be able to displace water from a metal surface, but care should be taken that the surface is not too wet.

A water-base coating will probably be applied full strength. It can also be sprayed or brushed. The recommendations of the manufacturer should be followed to ensure proper coverage.

A suitable thread-protecting compound should be applied and thread protectors screwed onto the threads before the pipe is coated. It may be desirable to coat the inside of the pipe with an oily coating and to use pipe caps to prevent water entry during storage.

If the coating is air sprayed, the pipe should be coated one layer at a time, making certain that the spray is adjusted to provide coverage without excessive loss. The pipe should be rolled, and the other side covered. The use of wood spacers between the layers of pipe allow any moisture to drain and dry during subsequent outdoor storage. Once the pipe is coated, sufficient drying time should be allowed before the pipe is moved.

Continuing Maintenance

The pipe should be inspected at preselected intervals to ensure that the coating is performing satisfactorily. The program can be modified, or the pipe can be recoated when needed. Complete records should be maintained so that corrosion prevention is an ongoing and effective process.
